Abstract

Introduction: The cerebrospinal fluid neurogranin (Ng)/β-site amyloid precursor protein-cleaving enzyme 1 (BACE1) ratio may reflect synaptic affection resulting from reduced beta-amyloid (Aβ) clearance. We hypothesize that increased Ng/BACE1 ratio predicts the earliest cognitive decline in Alzheimer’s disease.

Methods: We compared Ng/BACE1 levels between cases with subjective cognitive decline (n = 18) and mild cognitive impairment (n = 20) both with amyloid plaques and healthy controls (APOE-ε4+, n = 16; APOE-ε4-, n = 20). We performed regression analyses between cerebrospinal fluid levels, baseline hippocampal and amygdala volumes, and pertinent cognitive measures (memory, attention, Mini Mental State Examination [MMSE]) at baseline and after 2 years.

Results: Ng/BACE1 levels were elevated in both subjective cognitive decline and mild cognitive impairment compared to healthy controls. Higher Ng/BACE1 ratio was associated with lower hippocampal and amygdala volumes; lower baseline memory functions, attention, and MMSE; and significant decline in MMSE and memory function at 2-year follow-up.

Discussion: High Ng/BACE1 ratio predicts cognitive decline also in preclinical cases with amyloid plaques.

1. Introduction

In Alzheimer’s disease (AD), amyloid-β precursor protein (AβPP) metabolizes to Aβ-peptide, which precipitates in amyloid plaques [1]. Increased CSF neurogranin is related to synaptic loss, cognitive decline, and reductions in hippocampal volume in mild cognitive impairment (MCI) and dementia due to AD. Moreover, increased CSF neurogranin may distinguish AD from other neurodegenerative diseases [2–5]. Previously, we showed an inverse relationship between CSF neurogranin and the CSF Aβ1–42/Aβ1–40 ratio in MCI and dementia, suggesting that synaptic loss and AβPP metabolism may be linked [6]. Neurogranin is highly expressed in dendritic spines in hippocampal and amygdalar pyramidal cells and is linked to postsynaptic signal transduction [7,8]. The β-site amyloid precursor protein-cleaving enzyme 1 (BACE1) is linked to presynaptic AβPP metabolism [9,10]. Aβ-oligomers accumulate at synaptic terminals and may disrupt pyramidal cell N-methyl-D-aspartate (NMDA) receptors and postsynaptic Ca2+ homeostasis [11–13], putatively leading to synaptic loss. The APOE-e4 allele is a major genetic risk factor for AD and may enhance synaptotoxic oligomerization of Aβ-peptides [11,14,15].

As BACE1 is a rate-limiting step in the production of Aβ species [9,10], inhibitors are tested [16]. Clinical and biomarker studies in AD cases have shown contradictory results [17,18]. CSF Aβ1–42, as a marker for amyloid plaques (A), and CSF phosphorylated and CSF total tau, as markers for neurofibrillary tangles (T) and neurodegeneration (N), have been combined to the A/T/N stage marker for AD [19]. BACE1 levels have been shown to correlate with markers of neuronal degradation and neurofibrillary tangles (total and phosphorylated tau) [20], as well as synaptic loss (neurogranin), but not with Aβ [21], suggesting a relationship to neurodegeneration. Associated biomarkers can be explored as ratios, which, in some cases, have shown to offer better diagnostic performance, for example, the CSF Aβ1–42/Aβ1–40 ratio [22]. Recently, we compared several CSF measures as single analytes and ratios to cognitive decline and found that an increased ratio between CSF neurogranin trunc P75 and BACE1 (Ng/BACE1) was the only robust correlate of cognitive decline in MCI cases due to AD [21]. We propose that this ratio could sensitively reflect early synapse affection in AD linked to accumulation of toxic Aβ-oligomers at synaptic terminals.

Thus, we hypothesize that increased Ng/BACE1 ratio may herald development of cognitive deficits at a preclinical stage of AD [23,24]. To test this hypothesis, we included cases early in the AD trajectory (i.e., cases with subjective cognitive decline (SCD) and MCI with amyloid plaques) [19,25] and healthy APOE-e4+ and APOE-e4- control groups. We compared levels of Ng/BACE1 between the groups, relate Ng/BACE1 to AD biomarker severity using the A/T/N classification scheme [19], and explore relationships to baseline hippocampal and amygdala volumes and cognitive decline at 2-year follow-up.

2. Methods and materials

2.1. The Dementia Disease Initiation cohort

This study was a part of the Norwegian multicenter study, “Dementia Disease Initiation” (DDI) [26]. DDI uses a standardized protocol for participant selection, assessment, and disease-stage classification (SCD, MCI, and dementia) according to published criteria [25,27,28]. Participants were recruited from referrals to local memory clinics or self-referrals responding to advertisements in media, newspapers, or news bulletins. Healthy controls were recruited from spouses of participants with either MCI or SCD, volunteers responding to media advertisements or news bulletins, and from cognitively healthy patients who completed lumbar puncture for orthopedic surgery. Criteria for inclusion were age between 40 and 80 years and a native language of Norwegian, Swedish, or Danish. Exclusion criteria were brain trauma or disorder, including clinical stroke, dementia, severe psychiatric disorder, severe somatic disease that might influence the cognitive functions, intellectual disability, or other developmental disorders. The cohort described here was recruited between 2013 and 2017. For further description of the DDI cohort and methods, refer to the study by Fladby et al. (2017) [26]. Participants were assessed at baseline, and a subset had come to 2-year follow-up examination.

2.2. CSF collection and handling

Procedures were as described previously [26]. All CSF samples were analyzed at the Department of Interdisciplinary Laboratory Medicine and Medical Biochemistry at Akershus University Hospital, and samples from all other sites were frozen before sending to this laboratory following BIOMARKAPD SOPs as also described previously [29].

2.3. Protein biomarker measurements

Commercial enzyme-linked immunosorbent assays based on monoclonal antibodies were used to measure CSF levels of the following protein biomarkers: Aβ1–42, t-tau, and p-tau were determined using Innotest Aβ (1–42), Innotest h-Tau Ag, and Innotest Phospho-Tau (181P) (Fujirebio, Ghent, Belgium), respectively. BACE1 and neurogranin (trunc P75) levels were determined using kits from EUROIMMUN AG (Lübeck, Germany) as described in detail elsewhere [21]. All samples were analyzed in duplicates and reanalyzed if relative deviations (RDs) exceeded 20% and quality control samples with RD threshold of 15% controlled for interplate and interday variation.
2.4. Participant selection, study design, and A/T/N classification

For the purposes of the present study, we selected participants from the DDI cohort to construct four groups according to the study design criteria: (1) healthy controls with low risk of AD (n = 20, APOE-ε4-); (2) healthy controls with increased risk of AD (at least one APOE-ε4 allele and first degree relative with dementia, n = 16, APOE-ε4+); (3) SCD (n = 18) with CSF confirmed amyloid pathology; and (4) MCI (n = 20) with CSF confirmed amyloid pathology. In addition, participants were classified according to the A/T/N classification scheme for AD using CSF biomarkers [19]. A + denotes (CSF amyloid pathology only), A + N + (CSF amyloid pathology and neurodegenerative marker), and A + N + T + (CSF amyloid pathology, neurodegenerative marker, and marker of neurofibrillar tangles). The following cutoff values for CSF total tau (t-tau) and phosphorylated tau (p-tau) abnormality were applied according to the laboratory recommendations (modified from the study by Sjögren et al. [30]); t-tau is >300 pg/mL for age <50 years, >450 pg/mL for age 50–69 years, and >500 pg/mL for age ≥70 years and p-tau ≥80 pg/mL. An optimal cutoff at CSF Aβ1–42 < 708 for amyloid plaque pathology was determined following DDI PET [18F]-flutemetamol uptake studies [31]. Amyloid-positive cases were screened in accordance with the A/T/N classification scheme [19] before inclusion to ensure equal distribution of pathological markers between SCD and MCI groups. For demographics and study cohort characteristics, please see Table 1.

2.5. Neuropsychological battery

The neuropsychological battery included the Mini Mental State Examination (MMSE-NR) [32], verbal learning and memory recall (CERAD word list test) [33], psychomotor speed, and divided attention (trail-making test A and B [TMT A and B]). T-scores for the trail-making tests were calculated using published norms [34]. For the CERAD word list test, we used the normative performance of the DDI cohort control group [26] to calculate T-scores after a recent article that showed published norms not matching the younger and more educated DDI cohort [35]. A total of 42 of 74 baseline cases had available cognitive data at 2-year follow-up.

2.6. Magnetic resonance imaging

Magnetic resonance imaging (MRI) was performed at 7 sites, and 7 scanners were used; a total of 57 MRI scans were available for analysis. For group 1 (12 subjects), MRI was performed on a Philips Achieva 3 Tesla system (Philips Medical Systems, Best, the Netherlands). A 3D T1-weighted turbo field echo sequence (TR/TE/TI/FA = 4.5 ms/2.2 ms/853 ms/8° matrix = 256 × 213, 170 slices, thickness = 1.2 mm, in-plane resolution of 1 mm × 1.2 mm) was obtained. For group 2 (22 subjects), MRI was performed using

a Philips Ingenia 3 Tesla system (Philips Medical Systems, Best, the Netherlands). A 3D T1-weighted turbo field echo sequence (TR/TE/TI/FA = 4.5 ms/2.2 ms/853 ms/8°, matrix = 256 × 213, 170 slices, thickness = 1.2 mm, in-plane resolution of 1 mm × 1.2 mm) was obtained. For group 3 (3 subjects), MRI was performed using a Siemens Skyra 3 Tesla system (Siemens Medical Solutions, Erlangen, Germany). A 3D T1 magnetization-prepared rapid gradient-echo sequence (TR/TE/TI/FA = 2300 ms/2.98 ms/900 ms/9° matrix = 256 × 256, 176 slices, thickness = 1.2 mm, in-plane resolution of 1.0 mm × 1.0 mm) was obtained. For group 4 (11 subjects), MRI was performed using a Philips Ingenia 1.5 Tesla system (Philips Medical Systems, Best, the Netherlands). A 3D T1-weighted turbo field echo sequence (TR/TE/TI/FA = 7.63 ms/3.49 ms/937 ms/8° matrix = 256 × 256, 180 slices, thickness = 1.0 mm, in-plane resolution of 1.0 mm × 1.0 mm) was obtained. For group 5 (1 subject), MRI was performed using a Siemens Avanto 1.5 Tesla system (Siemens Medical Solutions, Erlangen, Germany). A 3D T1-weighted magnetization-prepared rapid gradient-echo sequence (TR/TE/TI/FA = 1190 ms/3.10 ms/750 ms/15° matrix = 512 × 512, 144 slices, thickness = 1.0 mm, in-plane resolution of 0.50 mm × 0.50 mm) was obtained. For group 6 (7 subjects), MRI was performed using a GE Optima Medical Systems 1.5 Tesla system (GE Healthcare, Chicago, IL). A 3D T1-weighted fast spoiled gradient-echo sequence (TR/TE/TI/FA = 11.26 ms/5.04 ms/500 ms/10° matrix = 256 × 256, 156 slices, thickness = 1.2 mm, in-plane resolution of 1.0 mm × 1.0 mm) was obtained. Finally, 1 MRI scan was performed using a Siemens Avanto 1.5 Tesla system (Siemens Medical Solutions, Erlangen, Germany). A 3D T1-weighted magnetization-prepared rapid gradient-echo sequence (TR/TE/TI/FA = 1700 ms/2.42 ms/1000 ms/15° matrix = 256 × 256, 144 slices, thickness = 1.2 mm, in-plane resolution of 1.0 mm × 1.0 mm) was obtained.

2.7. MRI segmentations and analyses

Volumetric segmentation was performed with the FreeSurfer image analysis suite version 6.0.0 (http://surfer.nmr.mgh.harvard.edu/). This includes segmentation of the subcortical white matter and deep gray matter volumetric structures [36]. For the hippocampus and amygdala, volumes from the left and right hemispheres were added, and relative volumes (per mL of total intracranial volume) were computed.

2.8. Statistical analysis

Normality was assessed through the inspection of QQ-plots, histograms, and the Shapiro-Wilk test of normality. To assess differences in biomarker levels, MRI-derived medial temporal lobe (MTL) volumes, cognitive tests, and demographics between groups, we performed one-way analyses of variance (ANOVA)s with planned comparisons for variables with normal distributions. For MTL volumes, ANOVA analyses were performed on standardized residuals after covariate regression correction for age, gender, and MRI scanner model. We performed Kruskal-Wallis test with Dunn’s nonparametric pairwise post hoc test to assess group differences in variables with non-normal distributions (CSF Aβ1–42, CSF t-tau, CSF t-tau, CERAD recall T-score, and MMSE). Nonparametric pairwise comparisons and ANOVA contrasts were performed in a hierarchical manner. If the high- and low-risk control groups were found equal on the relevant measure, we proceeded to compare SCD and MCI groups to controls (collapsed control group) and finally comparing the SCD with the MCI group. The dichotomous variable “gender” was assessed using a chi-square test. To compare levels of CSF neurogranin, CSF BACE1, and their ratio score to groups derived from the A/T/N groups, one-way ANOVAs with post hoc Bonferroni corrections were performed. Effect sizes are provided for ANOVA ($\eta^2$) and Kruskal-Wallis test ($\eta^2$) [37].

The impact of CSF biomarkers on MMSE scores were assessed using a multiple linear regression model controlling for age, and simple linear regression models were fitted to assess the relationship between biomarkers and age-adjusted T-scores for the different cognitive tests at baseline. Similarly, the relationships between biomarkers and MTL volumes were assessed using several multiple regression analyses controlling for effects of age, gender, and MRI scanner variant. Effect sizes for the overall regression models are provided ($R^2$).

Because CSF Aβ1–42 was used as core selection criteria in the study design, it was omitted as predictor from baseline regression analyses with cognitive and MRI variables. However, we assessed CSF Aβ1–42 as the predictor of cognitive changes at 2-year follow-up, CSF p-tau and t-tau demonstrated collinearity (variance inflation factor > 7). Thus, only CSF total tau was included in our regression models.

To assess the individual change in cognitive scores between baseline and 2-year follow-up, individual follow-up scores were subtracted from baseline scores. The resulting score was used to predict cognitive changes from baseline CSF biomarkers using linear regression models.

All analyses were performed in the Statistical Package for Social Sciences (SPSS) version 24.

2.9. Ethics

The regional medical research ethics committee approved the study. Participants gave their written informed consent before taking part in the study. All further study conduct was in line with the guidelines provided by the Helsinki declaration of 1964, revised 2013 and the Norwegian Health and Research act.

3. Results

3.1. Between-group CSF biomarker comparisons

We found significantly increased levels of CSF Ng/BACE1 in both SCD ($t(71) = 2.532, P < .05$) and MCI ($t(71) = 3.595, P < .001$) compared with controls.

3.2. CSF biomarkers in relation to A/T/N groups

Both CSF Ng (F(3,69) = 8.801, η² = .28, P < .0001) and CSF BACE1 (F(3,69) = 7.201, η² = .24, P < .0001), as well as CSF Ng/BACE1 ratio (F(3,69) = 6.656, η² = .22, P < .0001), were significantly different between A/T/N groups.

Levels of CSF Ng/BACE1 were increased in the A + N group (n = 30, M = .2102, standard deviation [SD] = .05) compared with controls (n = 35, M = .1642, SD = .03, P < .01). However, this was not shown for Ng or for BACE1 when measured separately. Both CSF BACE1 (n = 13, M = 2884, SD = 958, P < .05) and Ng levels (M = 580, SD = 164, P < .0001), as well as Ng/BACE1 level (M = .2061, SD = .04, P < .01), were elevated in the A + T + N group compared with individuals with normal CSF (Ng: M = 369, SD = 126; Ng/BACE1: M = .1642, SD = .03). In addition, Ng (n = 13, M = 580, SD = 164) was also elevated in the A + T + N group compared with the A + group (n = 15, M = 323, SD = 129, P < .0001). No significant differences between healthy controls with normal CSF and amyloid-positive (A+) individuals were found for CSF BACE1, Ng, or Ng/BACE1.

3.3. CSF biomarkers, APOE-e4, and MRI-derived medial temporal volumetry

All models include covariates controlling for age, gender, and scanner variant. When analyzing the entire sample (n = 57), higher CSF Ng/BACE1 levels were associated with reduced average hippocampal volume (β = −.334, P < .01, adjusted R² = 0.410, F(4,53) = 9.225, P < .0001). Similarly, higher CSF Ng/BACE1 was associated with lower performance in CERAD learning T-score (R² = .35, F(1,70) = 5.321, β = −.266, P < .05); CERAD recall T-score (R² = .97, F(1,70) = 7.535, β = −.312, P < .01); and TMT-A T-score (R² = .057, F(1,70) = 4.153, β = −.238, P < .05) (effect shown in Fig. 2). No other associations between CSF biomarkers or APOE-e4 carrier status and MTL volumetry were found. Significant regression coefficients are shown in Table 3. No overall significant differences in average hippocampal or amygdala volumes between groups were found. Please see Table 2 for details.

3.4. CSF biomarkers and APOE-e4 in relation to baseline cognitive performance

We found a significant inverse relationship between higher CSF Ng/BACE1 and lower performance in CERAD learning T-score (R² = .71, F(1,70) = 5.321, β = −.266, P < .05); CERAD recall T-score (R² = .97, F(1,70) = 7.535, β = −.312, P < .01); and TMT-A T-score (R² = .057, F(1,70) = 4.153, β = −.238, P < .05) (effect shown in Fig. 3). Moreover, when controlling for age (β = −.124, P = .31), we found that higher Ng/BACE1 (β = −.258, P < .05) also was associated with lower scores on the MMSE (adjusted R² = .078, F(2,70) = 4.044, P < .05).

No relationships between baseline cognitive measures and APOE-e4 carrier status or other CSF biomarkers were demonstrated. Statistically significant relationships were only found when analyzing the entire sample and are summarized in Table 3.
3.5. Baseline CSF biomarkers and APOE-ε4 carrier status predicting change in cognitive performance at 2-year follow-up

Lower baseline CSF Ng/BACE1 levels predicted practice effects (i.e., showing improved performance between baseline and follow-up), whereas increasing levels predicted less improvement and finally a decline between assessments in both CERAD learning T-score ($R^2 = 0.124, F(1,40) = 5.646, \beta = -0.352, P < .05$) and MMSE ($R^2 = 0.97, F(1,42) = 4.426, \beta = -0.312, P < .05$). A similar result was also obtained for Ng measured separately but only relating to the CERAD learning T-score ($R^2 = 0.104, F(1,40) = 4.622, \beta = -0.322, P < .05$). Similarly, CSF t-tau significantly predicted cognitive decline in CERAD learning ($R^2 = 0.170, F(1,40) = 8.217, \beta = -0.413, P < .01$) (effects are illustrated in Fig. 3). No relationships between 2-year cognitive change, APOE-ε4 carrier status, or other baseline CSF biomarkers were found. Significant relationships between baseline biomarkers and follow-up cognitive performance are summarized in Table 3.

4. Discussion

To our knowledge, this is the first study showing that Ng/BACE1 level is increased already at a preclinical stage of AD. Ng/BACE1 levels were equally increased in both
Aβ+ MCI and SCD groups compared with controls, and no difference in Ng/BACE1 levels between APOE-ε4+ controls. Closed circles = APOE-ε4− controls. Open triangles = MCI with amyloid plaques. Closed triangles = SCD with amyloid plaques. Abbreviations: CSF, cerebrospinal fluid; Ng, neurogranin; BACE1, β-site amyloid precursor protein-cleaving enzyme 1; APOE-ε4+/−, apolipoprotein E4 allele positive or negative; SCD, subjective cognitive decline; MCI, mild cognitive impairment.

Furthermore, when analyzing available 2-year follow-up cognitive scores, we found that lower baseline Ng/BACE1 levels predicted practice effects in the CERAD learning subtest at follow-up (i.e., showing improved performance) and increasing ratios predicted less recall, as well as attention/psychomotor speed (TMT-A) and global cognitive function (MMSE).
improvement and finally a decline in CERAD word list–learning ability. This relationship was also shown for CSF Ng measured separately, supporting previous findings [2,4]. Although a similar result was obtained with CSF t-tau as the baseline predictor, an inspection of the scatter plot indicated that the regression model may have been biased by a few subjects with extreme baseline CSF total tau values. This result suggests that the subjects with high baseline measures of neuronal degradation (CSF t-tau) may be at a more advanced stage of disease development and therefore show a steeper cognitive decline. This is in line with findings linking markers of neuronal degradation to disease severity [38]. In contrast, Ng/BACE1 levels may represent synaptic loss that is more closely tied to smaller increments of cognitive decline along the early Alzheimer’s trajectory, which may precede markers of significant neuronal degradation. This could explain why only the Ng/BACE1 level was related to baseline learning and memory function in our sample, possibly due to early synaptic loss in the hippocampus where neurogranin is highly expressed [7]. Moreover, although a higher Ng/BACE1 level was related to lower MMSE at baseline and decline at follow-up both in our previous [21] and present studies, Ng/BACE1 level was predominantly related to CERAD learning and memory recall. The MMSE contains word list memory items, and the observed relationship could be influenced by this shared measure. Interestingly, TMT-A, a measure of psychomotor speed and attention, was inversely related to CSF Ng/BACE1 level. This is in accordance with previous investigations showing that performance on the TMT-A is related to amyloid load in SCD cases and mixed samples of MCI and healthy subjects [39,40].

BACE1 and neurogranin have predominantly presynaptic [9,10] and postsynaptic roles, and neurogranin, in particular, is linked to the dendritic spine NMDA Ca\(^{2+}\)-Calmodulin second messenger complex [8]. Although synapse degeneration per se is not disease specific, the link between A\(\beta\) oligomerization, NMDA disruption, and spine Ca\(^{2+}\)-dysregulation [11,13] may confer an AD specificity to the Ng/BACE1 ratio marker and point to a postsynaptic A\(\beta\)-linked disease mechanism. This further strengthens the suggestion that NMDA antagonists may be protective in AD [41]. In this scenario, enhanced synaptotoxic polymerization of A\(\beta\)-peptides in APOE-\(\varepsilon\)-4 SCD and MCI cases will have a more rapid synaptic loss due to increased levels of synaptotoxic A\(\beta\) fibrils [11,14,15]. Although APOE-\(\varepsilon\)-4 carrier status did not significantly relate to medial temporal volumes or cognition in our sample, a large majority of the A\(\beta\)+ SCD and MCI cases (28 of 37) had at least one APOE-\(\varepsilon\)-4 allele. Moreover, APOE-\(\varepsilon\)-4 carriers with amyloid plaques had higher CSF Ng/BACE1 levels than noncarriers with plaques (data not shown). The Ng/BACE ratio was shown to increase with A/T/N-classified AD biomarker severity (i.e., moving from normal CSF...
An increase was also observed for both CSF BACE1 [20] and Ng [21] separately, supporting previous findings indicating a link to neurodegeneration. Though APOE-ε4 could enhance Ng/BACE1-related pathology through its interaction with Aβ [11,14,15], a larger material with more APOE-ε4− and Aβ+ MCI and SCD cases will be needed to establish ε4-allelic effects.

Both the link to cognitive measures and strong associations to volume reductions in pertinent MTL structures lend further support to a putative role of Ng/BACE1 as a biomarker for Alzheimer-related synaptic loss. CSF Ng/BACE1 level was similarly increased in the Aβ+ MCI and SCD groups, thus the SCD cases may harbor an active disease state, including progressive synaptic loss, experienced as a SCD that has yet to reach the threshold for clinical impairment.
Some limitations of this study need to be addressed. First, care must be taken in interpreting these findings due to a relatively small baseline sample size (n = 74), confined to small subgroups, and the even smaller sample size with available cognitive tests at a relatively short 2-year follow-up interval (n = 42). This may explain why we did not show an expected association between CSF Ng and hippocampal volume in our sample [2,4] or expected between-group differences in MTL atrophy in amyloid-positive subjects [42,43]. Second, although the National Institute on Aging and Alzheimer’s Association (NIA-AA) [28] recommends an MCI cutoff value of between −1 and −1.5 SD below the mean, we opted for a stringent cutoff at ≤−1.5 SD which can impact SCD/MCI group classification. However, cognitive performance in the SCD group was similar to that in the control group in our study, indicating that the SCD group’s cognitive performance was within the normal range. Finally, we did not include Aβ-negative SCD or MCI cases or explore potential differences between homozygote and heterozygote APOE-ε4 carriers to other APOE genotypes; both of which we plan to explore in subsequent articles.

4.1. Conclusions

To our knowledge, this is the first study showing that the Ng/BACE1 ratio is related to memory deficits and reduced MTL volumes in Aβ-positive preclinical cases and that Ng/BACE1 is significantly increased relative to controls in amyloid-positive subjects with SCD. These results warrant further studies investigating the role of Ng/BACE1 in the AD pathogenesis, potentially reflecting synaptic pathology due to an Aβ-linked disease mechanism. Although NMDA antagonists have been suggested to be protective [36], the present findings suggest that such intervention guided by an early Ng/BACE1 increase might be useful.
