

Paper V

29 **Abstract**

30 Predator populations with demographic cycles driven by multi-annual cycles of their key prey
31 resource can be expected to be “cyclic phase sensitive” to management actions. We explored
32 this by means of modelling in the case of the highly endangered Fennoscandian arctic fox
33 population which is driven by 4-year population cycles in small rodent prey. By using a
34 model in which the management action improved arctic fox vital rate through increased
35 resource availability, we show that arctic fox population growth was most improved when
36 management action was applied in the increase and decrease phase of the cycle. Except in the
37 low phase of the cycle, the growth rate was more affected when the management action
38 worked through improved reproduction than improved survival. There was a synergistic
39 effect to be gained by performing management action during multiple phases during a
40 demographic cycle. Thus we recommend that arctic fox conservation programs ought to be
41 continuous in time, but with the highest intensities of management action in the phases of the
42 cycle in which the target population is most prone to respond.

45

46 **Introduction**

47 Tundra food webs are often characterized by pronounced multi-annual population cycles of
48 small-sized herbivores, such as voles and lemmings (Elton, 1942). These herbivores
49 constitute key prey for many predators restricted to the tundra (Ims and Fuglei, 2005). Due to
50 the high degree of specialization in utilizing cyclic prey, the demography of tundra predators
51 is dependent on the phase of the prey cycle (Angerbjörn et al., 1999; Roth, 2003). When prey
52 availability is high, they respond instantly by increased reproductive output (in particular
53 litter size) resulting in rapidly increasing population size. Such demographic peak years,
54 however, are typically followed by a crash 1-2 years later due to prey density decreasing to
55 very low levels (Tannerfeldt and Angerbjörn, 1998). As a result, these predators often exhibit
56 pronounced cyclic population dynamics that hold the gross signature of the population cycle
57 of their dominant prey (Pitelka et al., 1955; Batzli et al., 1980; Angerbjörn et al., 1995;
58 Wiklund et al., 1999; Gilg et al., 2003; Roth, 2003).

59 The arctic is currently subject to large changes capable of disrupting the structure and
60 functioning of tundra ecosystems (Fuglei and Ims, 2008). Global warming, with the largest
61 impacts expected in polar areas (Hanssen-Bauer et al., 2005; Gillett et al., 2008), has been
62 highlighted as the major component of ecosystem change in this region (Callaghan et al.,
63 2004a, b). Predators may be particularly sensitive to such changes (Voigt et al., 2003; Ims
64 and Fuglei, 2005; Fuglei and Ims, 2008), especially specialist predators found exclusively in
65 tundra ecosystems where alternative prey are scarce (Fuglei and Ims, 2008). Several
66 specialist predators (e.g. Rough-legged buzzard (*Buteo lagopus*): Kjellen and Roos, 2000;
67 Snowy owl (*Bubo scandiacus*): Marthinsen et al., 2008; Arctic fox (*Vulpes lagopus*):
68 SEFALO, 2004) belonging to Arctic tundra ecosystems are now declining and significant
69 range contractions, in particular in the southern part of their distribution ranges, can be
70 expected (Ims and Fuglei, 2005).

71 On the Fennoscandian peninsula, which constitutes the south-western fringe of the
72 tundra biome in Eurasia, the arctic fox is already on the verge of extinction (Angerbjörn et
73 al., 1995; Dalén et al., 2006). The decline and range contraction of the Fennoscandian arctic
74 fox have, at least partly, been attributed to dampened peak abundances of cyclically
75 fluctuating vole and lemming populations (Ims and Fuglei, 2005; Henden et al., 2008) and
76 increased interspecific competition with the northward expanding red fox (*Vulpes vulpes*)
77 (Hersteinsson and Macdonald, 1992; Tannerfeldt et al., 2002; Elmhagen, 2003; Ims and
78 Fuglei, 2005; Killengreen et al., 2007). However, several other putative causes of the
79 “Fennoscandian arctic fox problem” have been proposed (Hersteinsson et al., 1989;
80 Hersteinsson and Macdonald, 1992). Several management actions are now being tried in an
81 attempt to reverse the decline of the arctic fox in all of the Fennoscandian countries
82 (Angerbjörn et al., 2007). These involve red fox culling (Norway, Sweden and Finland),
83 supplementary feeding (Sweden) as well as captive breeding with subsequent reintroductions
84 (Norway).

85 In general, management action aiming to reverse declines of endangered populations
86 ought to explicitly take into account factors that govern demography and temporal dynamics
87 of the population in question (Bradbury et al., 2001). For instance, potentially much can be
88 gained by targeting management action to moments in time when the population is most
89 responsive to any given action. Specifically, for species with pronounced multi-annual
90 population cycles, like the arctic fox, it might be expected that the effect of a management
91 intervention will depend on the particular phase of the demographic cycle. Hence, in this
92 study we analyse, by means of modelling, to what extent demographic perturbations exhibit
93 phase-dependent effects on arctic fox population growth. Based on this analysis we provide
94 recommendations on how management actions could be temporally allocated as to be most
95 effective.

96

97 **Methods**

98 **Modelling framework**

99 We assumed that management effort directed at arctic fox is concentrated in mountain tundra
100 areas of Fennoscandia where population cycles with recurrent moderate to high spring
101 densities of small rodents still prevail, as it is in such regions that the potential for arctic fox
102 recovery would be expected to be highest (Henden et al., 2008).

103 The current model held essentially the same characteristics as the model framework
104 developed by Henden et al. (2008) for linking arctic fox demography to small rodent
105 population dynamics. Arctic fox was modeled as a resident specialist with temporal variation
106 in vital rates driven by the amount of available rodent prey (Angerbjörn et al., 1999). Cyclic
107 small rodent dynamics was generated from a stochastic second order autoregressive model
108 (i.e. AR[2] model) (Bjørnstad et al., 1995; Stenseth, 1999). In the present analysis we
109 selected AR-coefficients that provided small rodent dynamics with a typical 4-year cycle
110 period. It is important to note that the periodicity in our model is statistical (Henden et al.,
111 2008) and not strictly mathematical. Because of this and the fact we use stochastic small
112 rodent dynamics as the driver of arctic fox demography, we have chosen a numerical as
113 opposed to a strictly periodic matrix model (cf. Caswell and Kaye, 2001; Caswell, 2005). The
114 resultant arctic fox dynamics was obtained from an age-structured demographic model in
115 which yearly matrices of demographic parameters are made dependent on the prevailing
116 rodent density (for more details see Henden et al., 2008). The simulated small rodent
117 dynamics in the present analysis yielded a long-term stochastic growth rate $\log \lambda = -0.0096$
118 (i.e. $\log \lambda = \frac{1}{T} \sum_{t=0}^{T-1} r_t$, where $T =$ time span, $r_t = \log(N_{t+1}/N_t)$ (cf. Caswell, 2001)) for the
119 arctic fox (10 000-year realization), when no management action was implemented in the
120 model.

121

122 **Relationship between management action and arctic fox vital rates**

123 It is well known that vital rates in arctic fox populations are highly dependent on the amount
124 of available natural resources such as small rodents (Tannerfeldt and Angerbjörn, 1998). On
125 the other hand there is still a scarcity of quantitative information in the literature about
126 demographic responses of arctic fox to management perturbation. Here we generally assumed
127 that management action affected population growth rate through increasing the amount of
128 resources available to the arctic fox. Resources in this context may constitute supplementary
129 food or access to resources or habitat that would otherwise be monopolized by the
130 competitively dominant red fox.

131 Due to the lack of knowledge about how management actions actually work to
132 improve arctic fox vital rates we investigated two contrasting scenarios of increased resource
133 availability resulting from management action (see Figure 1). In a *constant scenario* the
134 amount of resources was set to increase by a constant proportion of the prevailing resource
135 level in the ecosystem (i.e. as determined by the small rodent dynamics). In the other scenario
136 we assumed that management action was most effective at low natural resource levels and
137 that the proportional increase due to the action decreased with increased natural resource
138 levels. This *diminishing return scenario* could, for instance, either result from higher
139 exploitation of artificially supplied food when more preferential natural food sources are
140 scarce or from more effective culling when red fox are attracted to hunters' baits at low
141 natural resource levels. Moreover, to assess the possibility that the magnitude (i.e.
142 proportional increase) of the management induced increase in resource availability may have
143 a disproportional effect on arctic fox growth rate, we simulated and compared three levels of
144 the magnitude of change in the response scenarios (i.e. *diminishing return scenario*
145 (maximum levels): 20%, 50% and 100% , *constant scenario*: 10%, 25% and 50%). Finally,

146 due to uncertainty about which vital rates are most affected by management action we ran the
147 simulations assuming that (1) only reproductive parameters were affected; (2) only survival
148 rates were affected and (3) all vital rates were affected by the management action.

149 A very important feature of the arctic fox model is the logistic functions relating
150 prevailing resource levels (i.e. small rodent density) to arctic fox vital rates (see Henden et
151 al., 2008 for more details). These functions cause the vital rates to respond non-linearly to
152 increased resource availability (Figure 2). Specifically, on the background of low resource
153 levels (and consequently low demographic rates) a given proportional increase in resource
154 availability will result in a larger demographic response than the same proportional increase
155 at high natural resource levels (and higher baseline demographic rate) (see Figure 2).

156

157 **Defining cyclic phases**

158 To be able to pinpoint the management actions to a specific phase of the small rodent cycle
159 (and thus the demographic cycle of the arctic fox), we used a simple, practical rule to predict
160 the next phase (t+1) based on the previous 3-4 years of the dynamics (see Table 1 and S1 in
161 the appendix for more details). Owing to the stochastic nature of the AR[2] model used to
162 generate small rodent dynamics the rule employed for predicting cyclic phases led to a certain
163 frequency of misclassification. Even in empirical time series of small rodent dynamics there
164 is usually a considerable variation around the mean periodicity and amplitude of the cycles
165 (Hanski et al., 1993). In our simulations there was a tendency to over-estimate the frequency
166 of increase and decrease phases (i.e. ~ 0.27) in the underlying small rodent time series as
167 compared to the expected equal frequency of 0.25 for each phase in the 4-year cycle. The
168 effect of management action over 10 000 years is confounded by the number of years in each
169 phase. For instance, if a phase consists of more years, the effect on $\log \lambda$ will be higher and
170 vice versa. In order to correct for this bias we scaled all $\log \lambda$ values according to

171

172
$$\log \lambda = \frac{\log \lambda_u}{Freq_{emp}} * Freq_{the} \quad , \quad \text{eqn 1}$$

173

174 where $\log \lambda_u$ denotes the unscaled growth rates, $Freq_{emp}$ denotes the realized frequency of a
175 specific phase in the small rodent time series and $Freq_{the}$ denotes the expected frequency (i.e.
176 0.25).

177

178 **Quantifying the effect of management action: Elasticity analyses**

179 In order to evaluate the effect of management action on the population growth rate of arctic
180 fox, we calculated the phase-dependent empirical elasticity of $\log \lambda$ to management action
181 (referred to hereafter as E_{tot}) following Nichols and Hines (2002, equations 27 and 28):

182

183
$$E_{tot} = \frac{\Delta \log \lambda}{\Delta Action} = \log \lambda_{managed} - \log \lambda_{non-managed} \quad , \quad \text{eqn. 2}$$

184

185 where $\Delta \log \lambda$ is the difference in $\log \lambda$ between a managed and a non-managed population. Δ
186 $Action$ was here taken as one (i.e. 1 (action) vs. 0 (no action)), but could equally represent the
187 effort of managers in rising resources to a specific level (e.g. a 20% increase) or the unit cost
188 attributed to a specific increase in resource availability (cf. Nichols and Hines, 2002). As
189 mentioned above, the total elasticity of $\log \lambda$ to management action was mediated through
190 increased resources. However, the corresponding effect on the population growth rate was
191 dependent on the ability of arctic fox to convert increased resource availability into increased
192 demographic rates. Thus, E_{tot} could be decomposed into two components:

193

194
$$E_{tot} = \frac{\Delta \log \lambda}{\Delta Action} = \frac{\Delta \log \lambda}{\Delta Res} * \frac{\Delta Res}{\Delta Action} = E_1 * E_2 \quad , \quad \text{eqn. 3}$$

195

196 where ΔRes denotes the phase-specific difference in mean resource availability between the
197 managed and non-managed population. Thus, the second component (referred to hereafter as
198 E_2) reflected the ability of management action to raise resources available to arctic fox in a
199 specific phase of the cycle, whereas the first component (referred to hereafter as E_1)
200 represented the phase-specific ability of arctic fox to convert this increase in resource
201 availability into a demographic response (i.e. increased vital rates). Finally, we assessed to
202 what extent management actions in more than one phase per cycle would yield synergistic
203 effects on $\log \lambda$. Thus, we simulated actions in all combinations of two phases and compared
204 the resulting values of $\log \lambda$ (i.e. synergistic effect) with the sum of $\Delta \log(\lambda)$ from the two
205 respective phases as obtained from the single phase simulations (i.e. additive effect).

206 All simulations were based on a 10 000 year time series to obtain robust measures of
207 the long term stochastic growth rate (cf. Caswell, 2001) of arctic fox.

208

209 **Results**

210 The elasticity of the growth rate to management action (E_{tot}) was, as expected, highly
211 dependent on the phase of implementation (Figure 3). In general the patterns of phase-
212 specific elasticities were very similar for the two response scenarios; the highest impact of
213 management action was obtained in the increase phase, closely followed by the decrease
214 phase. The main difference in the patterns between the two response scenarios was in the low
215 and peak phase due to a somewhat higher elasticity in low compared to peak phase for the
216 *diminishing return scenario* compared to the *constant scenario*, where the opposite was the
217 case (Figure 3i). In both scenarios the elasticity to management action (E_{tot}) was mainly
218 driven by the phase-specific elasticity of λ to increased resource availability (E_1 ; Figure 3ii).

219 Simulations quantifying the effect of management actions on reproduction and survival
220 separately showed (for both scenarios) that reproductive output had higher impact on arctic
221 fox growth rate than survival in all phases except in the low phase (Figure 3).

222 Increasing the magnitude of change in resource availability from management action
223 increased, as expected, the elasticity of the growth rate (Table 2), but without changing the
224 phase-specific pattern. The increase in E_{tot} was mainly ruled by the increased resource
225 availability as derived from management action (i.e. E_2). However, at the largest magnitude
226 of increase (i.e. 100% and 50%, respectively) this pattern was slightly counteracted by the
227 reduced ability of increased resource availability to mount a further increase in demographic
228 rates (E_1 , Table 2, see also Figure 2), especially in the peak and increase phases of the
229 demographic cycle.

230 There was, generally, a substantial synergistic effect of implementing management
231 action in combinations of two phases per cycle as compared to simply adding the effects over
232 the same two phases as derived from single-phase perturbations (Table 3). There was not
233 much difference in the magnitude of the synergistic effect between the different combinations
234 of phases.

235

236 **Discussion**

237 Although several management actions presently are conducted to reverse the regional decline
238 of the arctic fox in Fennoscandia, no attempt has yet been made to evaluate how these actions
239 could be temporally allocated so as to maximize their impact. Such an evaluation appears to
240 be particularly relevant for populations with pronounced resource driven multi-annual
241 demographic cycles. In such cases the effect of management action could be expected to be
242 “cyclic phase-dependent”. Indeed, using a modelling approach we confirmed this
243 expectation. Generally, management action appeared to be most effective when applied in the

244 increase and decrease phase of the cycle. In these phases (and in particular in the increase
245 phase) it was possible through management action to realize some of the intrinsically large
246 reproductive potential possessed by the arctic fox.

247 In lack of specific information about how different management actions specifically
248 affect arctic fox vital rates we assumed a rather generalized demographic response acting
249 through improved resource availability. This assumption seems reasonable since lower
250 resource availability, either owing to dampened small rodent cycles or displacement from
251 high quality habitats by red fox, has been suggested to underlie the most recent decline of the
252 arctic fox in Fennoscandia (Tannerfeldt et al., 2002; Ims and Fuglei, 2005; Henden et al.,
253 2008). Moreover, the fact that the general pattern of the phase-dependent elasticities was
254 relatively unaffected by both the magnitude and the functional aspects of the resource
255 availability released by management action, indicates that the predictions from our model are
256 relatively robust. What appears to be among the most critical aspect of management action,
257 and which is in need of empirical information, is whether any given action acts to improve
258 arctic fox survival and/or reproductive parameters. Our analysis suggests that actions that
259 improve reproductive output usually have the largest effect on arctic fox growth rate. Only in
260 the low phase of the cycle the elasticity of the growth rate was more impacted by improved
261 survival than reproduction. The overall importance of reproductive parameters in the arctic
262 fox capacity for growth is also reflected by the exceptionally high variance in such
263 parameters observed in natural populations (Tannerfeldt and Angerbjörn, 1998; Angerbjörn
264 et al., 2004). Survival rate, in particular in adult age classes, appears to be much less variable
265 (cf. Meijer et al., 2008).

266 Although we have here identified specific phases in the demographic cycle of arctic
267 fox populations in which management efforts are likely to be most effective, we have also
268 highlighted the importance of allocating the efforts over multiple phases. Indeed, as evident

269 from the synergistic effect resulting from combined actions over two phases per cycle there is
270 an extra gain to be obtained by spreading the effort in time. Thus, a general recommendation
271 to be derived from the present study is that management programs should be run as
272 continuously as possible, but with the highest intensity allocated to phases of the
273 demographic cycle in which the arctic fox population is most prone to respond positively to
274 management action. Accordingly, we advise that under low phase actions directed towards
275 increased survival should be prioritized, whereas actions during increase and decrease phases
276 should be directed towards reproduction. More explicit, we suggest that actions aimed at
277 reproductive rates could be focused on the breeding territories during late winter/spring and
278 summer such as supplemental feeding and red fox control, whereas actions aimed at
279 promoting survival should be spread out over time and space. Such a phase-sensitive
280 management strategy should be feasible to implement in most conservation programs. The
281 simple empirical rule we applied for identifying cyclic phases worked well in the framework
282 of the simulated rodent dynamics with a great deal of stochastic variation (Appendix, S1).
283 This was also the case when tested on an empirical time series (Appendix, S1) derived from
284 vole trapping in Kilpisjärvi, northern Finland (Henttonen and Wallgren, 2001). Thus,
285 adequately monitored natural rodent populations are likely to provide an equally good basis
286 for identifying phases. Moreover, since arctic fox population dynamics tightly mirrors that of
287 their small rodent prey even monitoring data on the arctic fox population itself could serve as
288 an adequate predictor of the next phase of the demographic cycle. In addition, monitoring
289 arctic fox activity on dens during winter and early spring may provide important updated
290 information on the likely state of the next phase than that derived solely from predictions
291 based on the previous year(s) of small rodent/arctic fox dynamics.

479

480 **Table 1.** Practical rule to predict the next phase of small rodent dynamics from knowledge of
481 the dynamics in the past 4 years. This rule comprises a set of logical statements that in sum
482 will yield the likely next phase of the small rodent dynamics.

483
484

485 **Table 2.** Phase dependent elasticity of $\log \lambda$ to management action for A) the **Diminishing**
486 **return scenario** and B) the **Constant scenario**. **Elasticity of λ to resource availability** (E_1)
487 denotes the demographic response of arctic fox to the increase in resource level. **Elasticity of**
488 **resource availability to management action** (E_2) denotes the ability of management action
489 to raise resource availability for the arctic fox. **Elasticity of λ to management action** (E_{tot})
490 denotes the overall effect of management perturbation on the population growth rate of arctic
491 fox, where E_{tot} is the product of E_1 and E_2 . **Vital rates** denote which set of vital rates are
492 affected by the management perturbation and **Impact** denotes the maximum possible increase
493 in resource availability possible from management perturbation. **Low** denotes the low phase,
494 **Increase** denotes the increase phase, **Peak** denotes the peak phase and **Decrease** denotes the
495 decrease phase of small rodent dynamics when management perturbations are implemented,
496 respectively.

497
498

499 **Table 3.** The effect on $\log(\lambda)$ of management actions implemented in two phases
500 simultaneously during the demographic cycle of arctic fox compared to the additive effect of
501 summing the respective phases from single phase simulations for A) The **Diminishing**
502 **return scenario** and B) the **Constant scenario**. **Vital rates** denote which set of vital rates are
503 affected by management action. **Effect** denotes the synergistic or additive effect of two phase
504 implementation and **Impact** denotes the magnitude of change in resource availability
505 achievable from management action. The different **Phase** compositions denote which phases
506 are perturbed simultaneously in each simulation.

507
508

509 **Figure 1.** Two scenarios applied in the analysis linking management action to an increase in
510 resource availability to the arctic fox, depending on the prevailing rodent density. Gray
511 stippled line (i.e. at 1.25) denotes the constant scenario, whereas the black solid line denotes
512 the diminishing return scenario. Horizontal lines at the bottom of the figure depict the range
513 (i.e. 95% of values, between the 0.025 and 0.975 quantiles) of resource density after
514 management action in the respective phases of the demographic cycle of arctic fox for the
515 two response scenarios. The figure represents a simulation with a maximum magnitude of
516 change equal to 50% (i.e. proportional increase of 1.5) for the decreasing scenario and a
517 constant magnitude of 25% for the constant scenario.

518
519
520
521
522
523
524
525

526 **Figure 2.** Diagram demonstrating how increased resource availability translates nonlinearly
527 to arctic fox vital rates relative to the baseline demographic rates as determined by the
528 prevailing small rodent density. Black solid line denotes the logistic functional relationship
529 linking prevailing small rodent density to arctic fox vital rates. Black filled circles denote two
530 baseline small rodent densities and the gray filled circles denote the corresponding baseline
531 demographic rates. Black arrows denote the same proportional (i.e. 50%) management
532 induced increase in resource availability for the two baseline small rodent densities. Gray
533 arrows denote how this increase in resource availability transfers nonlinearly to increased
534 vital rates of the arctic fox through the logistic curve.

535
536

537 **Figure 3.** Phase-specific elasticity for panels A) the Diminishing return scenario and B) the
538 Constant scenario. Subplots denote i) Elasticity of λ to management action (i.e. E_{tot}), ii),
539 Elasticity of λ to increased resource availability (i.e. E_1) and iii) Elasticity of increased
540 resource availability to management action (i.e. E_2). The partial contribution from survival
541 and reproductive parameters make up the bars, except for iii) where the elasticity of resource
542 increase to management action is the same irrespective of the set of vital rates simulated.
543 Note that the scale of the y-axis is different between the three plots in each panel, and that
544 elasticities represent simulations with a maximum magnitude of change of 20% (Table 2).
545 Also, the sum of the elasticity of survival and reproductive rates is not exactly equal to the
546 elasticity of all rates, due to the use of numerical versus theoretical elasticities.

547
548
549

Appendix:

550 **S1.** Performance of the rule for predicting the next phase of the cycle (see Table 1). A)
551 Simulated (i.e. AR[2]-model generated) time series and B) Kilpisjävri small rodent time
552 series (Henttonen and Wallgren, 2001). Left y-axes and the corresponding black lines denote
553 the prediction of the different phases, whereas the right y-axes and the corresponding red
554 lines denotes the respective time series to be predicted. Filled squares denote the prediction of
555 the specific phases, where red squares denote low, blue denote increase, green denotes peak
556 and black denote decrease phase, respectively.

Table 1.

The set of statements that form the classification rule		
No.	Statement	Next Phase
1.	If previous year was a peak, and density declines	Decrease phase
2.	If previous year was a peak, and density increases	new Peak phase
3.	If density is declining this year and declined the year before	Low phase
4.	If density increase this year, but decreased the year before	Increase phase
5.	If density increase this year as well as the year before	Peak phase
6.	If density decreases this year, but increased the year before	Decrease phase
7.	If none of the above	Low phase, by default
