ACKNOWLEDGEMENT

I would like to extend appreciation & gratitude to all respondents who gave their valuable time, voluntary support and shared their personal experience to make the research possible.

I would like to express my sincere gratitude and indebtedness to Dr Luai A. Ahmed for his expert guidance and constant supervision ever-abiding encouragement and timely help. His tactful suggestion and kind help enabled me to complete this project work successfully.

I am also very grateful to the Professor, Dr Elese Kolmen for her effort, encouragement and support to make this thesis success. Further I am thankful to Madhav panta, Pradeep Shrestha, M Shakya and all the staff at related ART centers for their valuable support during the data collection period. I am indeed grateful to Tromso University department of public health for providing fund for this research.

Last but not the list I would like to extend my sincere thanks to all the faculty members, family and friends for their suggestion and moral support.

Rajesh Shigdel
ABSTRACT

Objective: To determine the prevalence and predictors of antiretroviral therapy adherence among HIV/ AIDS patients in Kathmandu district.

Methods: A cross-sectional study of 316 HIV-positive individuals receiving antiretroviral therapy from three ART sites in Kathmandu districts was done from January 2012 to February 2012. The participants were interviewed and answered questions about socio-demographic status and antiretroviral therapy during the past week. Participants were considered adherent if they reported taking ≥95% of their medication as prescribed. The association between explanatory variables and adherence was measured using logistic regression and was reported as odds ratio (OR) with 95% confidence interval.

Results: Out of the 316 participants, 64.6% (n=201) were men and 35.4% (n=112) were women. The adherence prevalence of the study participants was 86.7% (n=274). The adherence prevalence in men and women were 84.3 % and 91%, respectively. Age (OR 1.04; 95% CI 1.00-1.09), time taken to reach ART center (OR 1.38; 95% CI 1.12-1.71), past illegal drugs use (OR 3.98; 95% CI 1.71-9.24), side effects (OR 4.88; 95% CI 1.09-21.8), were all independently and negatively associated with adherence. Whereas, use of reminder tools (OR 3.45; 95% CI 1.33-8.91) was independently and positively associated with adherence.

Conclusion: The prevalence of adherence found in this study is encouraging. Age, time taken to reach ART center, side effects, illegal drugs use and not using reminder tools present barriers for adherence to ART. Improving adherence requires interventions which recognize these barriers.

Key Words: Antiretroviral Therapy (ART), Adherence, Kathmandu, AIDS patients

1. INTRODUCTION

1.1. Global Epidemiology of HIV/AIDS

The first case of the Acquired Immune Deficiency Syndrome (AIDS) was reported in 1981 in the USA. Within a short period of time the spread of the Human Immunodeficiency Virus (HIV) and AIDS has reached a pandemic form [1]. Now HIV has become one of the world's leading infectious killers, claiming more than 25 million lives over the past three decades [2]. Based on recent UNAIDS World AIDS day report, there are 34 million people living with AIDS across the globe, 2.67 million people became infected with the virus and 1.8 million people died of HIV-related causes at the end of 2010. The same report shows increased access to HIV treatment in last few years, and decreased new HIV infections and AIDS-related deaths to the lowest levels since the peak of the epidemic. New HIV infections were reduced by 21% since 1997, and deaths from AIDS-related illnesses decreased by 21% since 2005 [3]. These reports support the fact that the global response to AIDS has demonstrated tangible progress toward the achievement of Millennium development goals 6 (MDG 6) [4]. However, AIDS had become one of the leading causes of death among adults in sub-Saharan Africa. This region with only 12% of the global population remains as the most heavily affected by HIV&AIDS in 2010. An estimated 68% of all people living with HIV resided in sub-Saharan Africa [5]. The prevalence of HIV is comparatively lower in Asia than the other continents, but the actual size of the Asian population makes it the second largest grouping of people living with HIV [5].

The first HIV case in the Asia-Pacific region was reported from Thailand in 1984. Within a few years, HIV continues to spread in this region [6]. In late 2010, estimated 270 000 (230 000–340 000) new HIV infections are there in South and Southeast Asia. This was 40% less than at the epidemic’s peak in 1996 [1]. According to data published by World Bank, between
2 and 3.5 million people in South Asia were living with HIV and AIDS in 2010. India alone accounts for 2.5 million people living with HIV and AIDS [7].

1.2 Global Response to HIV/AIDS

Introduced in 1986, Zidovudine (ZDV) was the first antiretroviral drug for treatment of HIV infected patients. Few years later, other nucleoside reverse transcriptase inhibitor (NsRTIs) drugs such as Didanosine (ddI), Lamivudine (3TC), and Stavudine (d4T) were introduced. These days, new classes of drugs; the protease inhibitors (PI) and non-nucleoside reverse transcriptase inhibitors (NNRTI), are available in order to prevent the emergence of resistance and to strength the immune function. Now, standard antiretroviral therapy (ART) consists of the combination of at least three antiretroviral (ARV) drugs [8, 9]. The ART has provided a relief to HIV-infected individuals by reducing the likelihood of opportunistic infection rather than curing the disease. Moreover, it has played an important role in decreasing the mortality and morbidity of related to HIV/AIDS [5, 10].

In 2003, the World Health Organization (WHO) had launched the ambitious target to access ART for 3 million people living in low- and middle-income countries by 2005. Though, the target was not achieved until 2007, but it was useful for expanding the ART coverage. Again, In 2011, the international community committed achieving universal access by 2015 and it is also a part of millennium development goal [11]. During the last few years, global effort had been made to scale up the antiretroviral therapy in the developing countries. By the end of 2010, approximately 6,650,000 people were reviving antiretroviral therapy in low and middle income countries [12]. Sub-Saharan Africa had the greatest increase in the absolute number of people receiving ART. The estimated coverage of ART in low and middle-income countries was 47% at the end of 2010, compared to 39% at the end of 2009 [5]. It is estimated that around 2.5 million deaths have been averted in low and middle-income countries since
1995 after introducing the antiretroviral therapy. In addition to decreasing HIV-related mortality and morbidity, scientific evidence shows that increased access to ART is also reducing the risk of HIV transmission to sexual partners by 96% [13,14].

1.3 Epidemiology and response to HIV/AIDS in Nepal

1.3.1 Country profile

Nepal is a small landlocked country with multicultural, geographical richness and diversity. It lies in the central Himalayas wedged between India to its east, south and west and China to its north. It covers an area of 147,181 km². It is a homeland of 30 million people, and agriculture is the major source of economy [15]. Administratively, the country is divided into 75 districts, 58 municipalities, and 3,915 Village Development Committees (VDCs). There are over 100 ethnic groups and 92 spoken languages [16]. The country has seen many political changes in its modernization process, which have resulted in major social and economic transformations. Besides that, factor such as poverty; political instability, deprivation, and discrimination are core underlying causes of poor development. Despite the above hindering factor and decade-long conflict Nepal is close to achieving several of the eight MDGs by 2015 [17]. Demographic profile of the country is presented in Table 1.

1.3.2. Epidemiology of HIV/AIDS in Nepal

According to the World Bank, “HIV in Nepal is extremely heterogeneous, with respect to the most-at-risk populations (MARPs), geographic distribution, and risk factors in different geographic regions” [7]. Since the first case of AIDS was reported in 1988, HIV in the country has evolved from “low to concentrated epidemic” [19]. Recent report shows that approximately 50,200 adults and children are living with HIV. The overall prevalence of HIV among adult, aged 15-49 years was estimated to be 0.30% [20]. Of this, an estimated 28.5%
were women and 58% were men belonging to reproductive age group. “However, World Bank report suggests that due to limitations of Nepal’s public health surveillance system, the actual number of infections is could be even higher” [7].

The major mode of transmission of HIV is through heterosexual behavior, where four out of every five infections, are transmitted sexually [7]. The estimated HIV prevalence amongst MARPS are: Male labour migrants (27.6 %), Men who have sex with men (MSM) (14.4 %), Male sex workers, transgender and their clients (MTCs) (7.2 %), female sex worker (FSW) (1.5%). client of female sex workers (4.4 %), injection drug users (IDU) (2.2%) and the remaining male and female populations who are identified as low risk population accounted for 16% and 27%, respectively [21,22]. Generally, FSW, IDU and MSM are considered as key population who are at a higher risk of acquiring HIV infection. While the clients of sex worker and male labour migrants are playing the role of bridging populations for transmission of HIV between high risk group and the general population [23].
New HIV infections have significantly reduced since last 5 years due to targeted prevention intervention among MARPS. However, it is still a challenge to improve the effective coverage of prevention intervention and to achieving the national target of reducing the new HIV infections into half by 2015[23].

1.3.3 Nepal’s Response to HIV/AIDS

The Government of Nepal started HIV/AIDS treatment program since 2004 and started giving free ART drugs from Teku Hospital only for limited number of patients.[24] Now, the government is providing free of cost ART service and counseling for all those in need, through different ART centers and ART Sub-center (in public hospitals and other non-governmental organizations). There is a national ART guidelines and standard operating procedure for the clinical management of ART in Nepal [10,24] Nepal’s first ART center, Teku is operating with different service outlets such as counseling, voluntary counseling and testing (VCT), pre-ART and ART. During the last few years, the number of patients on ART has consistently increased following WHO recommended ART eligibility to patients with CD4 below 350 cells/mm$^3$ [15]. The total ART coverage reached 23.7 % by December 2011, and 6,051 adults, and 432 children were accessing ART from 26 ART centers and 10 sub-ART centers throughout the country. Similarly, CD4 count service is available at 13 centers while 4 centers have CD4 caliber. Among subjects with advanced HIV infection who are currently receiving ART, 57.8% are males, 42% are females and 0.92% are of third genders [24]. In the past few years, the HIV prevention program has focused the high risk group population and consequently Nepal has been successful in reducing the incidence of HIV infection through both providing treatment and preventing vertical (mother-to-child) transmission (MTCT) of HIV. Furthermore, the Government of Nepal has shown its commitment for the virtual elimination of MTCT of HIV by 2015. Different activities and
programs have been implemented through ART centers to improve the adherence to ART and follow-up of people living with HIV/AIDS (PLHIV). Some of the examples are establishment of community and home-based care (CHBC) site, Community Care Centers (CCCs) to provide care, support and treatment to PLWA in some districts. However, it is still challenging to a resources-limited country like Nepal, to achieve 80% of universal access to those who require ART in the next few years [23].

There are several regimens available with acceptable antiretroviral potency, generally, the following regimens: Zidovudine/Lamivudine/Efavirenz, Zidovudine/Lamivudine/Nevarapine, Stavudine/Lamivudine/Nevarapine, Stavudine/Lamivudine/efavirenz, are commonly used as first line drugs and Tenofovir/Lamivudine/Efaverenz, Tenofovir/Lamivudine/Efaverenz used as second line drugs in Nepal. Furthermore, the choice of regimen depends on availability, convenience and likelihood of adherence, regimen potency, tolerance etc. [8].

1.4. Adherence to ART

In the context of treatment with medications, adherence is defined as a patient’s ability to follow a treatment plan, take medications at prescribed times and frequencies, and follow restrictions regarding food and other medications [25]. Adherence is a primary determinant of the effectiveness of treatment [26]. It is also considered as a major predictor of the survival of individuals living with HIV/AIDS [27]. More than 95% adherence is required in ART in order to prevent the emergence of resistant viral strains. In practice this degree of adherence requires a patient on a twice-daily regimen to not miss or substantially delay more than 3 doses of antiretroviral medications per month [8]. Adherence to antiretroviral therapy (ART) has been strongly correlated with HIV durable viral suppression, reduced destruction of CD4 cells, reduced rates of resistance, increased in survival, and improved quality of life [27,28].
The availability of antiretroviral treatment (ART) has dramatically improved the prognosis and quality of life for HIV/AIDS patients, and reduced the rate of disease progression and death. However, increased access to ART has been accompanied by increasing unsatisfactory adherence levels and the potential risk of drug resistance. Maintaining an optimal adherence level for a long term poses a significant challenge for both patients and health care provider [29]. Suboptimal treatment can lead to drug failure with the latter resulting in spread of drug resistant mutation. Consequently, it can create dangerous public health situation and decrease the success of available HIV treatment [30]. Moreover, if people living with HIV require second-line treatment, it can be ten times more expensive than first line drugs. It also leads to increased hospitalization rate, increased the cost of health care, effects on human resources productivity, disruption of family and communities and morbidity and mortality in developing countries [31].

There are various factors affecting adherence, which generally are related to characteristics of the patient, the regimen, the clinical setting, the society and the relationship between the service provider and the patient [8, 27]. Presently, poor adherence to treatment regimen remains a major obstacle in the fight against HIV/AIDS [28]. Without proper treatment and prophylaxis, HIV/AIDS presents a significant challenge to global tuberculosis (TB) control. Whereas, TB is a leading preventable cause of death among people living with HIV and it is estimated that without proper treatment, the lifetime risk of developing active tuberculosis among the people with HIV is 30 times as compared to the people without HIV [1].

1.4.1. Predictors of Adherence

a) Patient Characteristics

Patient’s related factors are the most important factors that influence their adherence and are under the patient’s control. Understanding them is important in order to improve the
adherence [32]. In addition, the cultural aspects of the patient’s health beliefs and life goals are also important influential factors in the context of treatment adherence [33].

Studies have shown controversial associations between socio-demographic factors and adherence behavior.[28,29,30] Though some studies have found that male gender, older age, higher income, higher education, and literacy correlate with better adherence [34]. More consistent associations are found between certain psychosocial factors and adherence behavior. Common predictors of non-adherence include depression/psychiatric morbidity, active drug or alcohol use, side effect, stigma and discrimination, stressful life events, lack of access and social support etc [35].

b) Treatment regimen

Characteristics of the medical regimen constitute another important correlate of adherence. Factors related to the treatment regimen include the number of pills prescribed, the complexity of the regimen (dose frequency and food instructions), the specific type of antiretroviral drugs, and the short and long-term medication side effects [35]. Adverse medication side effects, complexity of daily routines, pill burdens, lowered genetic barriers leading to drug-class resistance, and long-term uncertainties are all major factors that challenge a patient’s ability to successfully adhere to a regimen [36].

c) Patient-provider relationship:

Patient-provider relationship can also affect adherence. Trust in the provider and clinical staff, good communication, adequate education about medication, the provider’s willingness to include the patient in the decision-making process, the affective tone of relationship may affect the adherence, including the patient’s overall satisfaction [35]. Overall patient satisfaction with medical care has been found to correlate with increased adherence. The perception of providers as being warm and caring has been related to greater adherence [33].
d) Disease characteristics

Disease characteristics include the stage and duration of HIV infection, associated opportunistic infections, and HIV-related symptoms [35]. Some studies described an increased adherence in those with the history of opportunistic infections. This shows that prior opportunistic infections increased adherence suggesting that illness severity motivated patient’s adherence [36, 37].

1.4.2. Measurement of adherence

There is no gold standard to access the adherence, therefore, it is difficult to accurately measure adherence to therapy [27]. However, there are many validated tools and strategies to access adherence. Currently, available methods for adherence assessment can be grouped into two major categories (Table 2) [38].

Table 2: Different measures of adherence

<table>
<thead>
<tr>
<th>Direct Measures</th>
<th>Indirect measures</th>

</tr>
<tr>
<td>Medication Event Monitoring System (MEMS)</td>
<td>Visual analogue scale (VAS)</td>
</tr>
<tr>
<td></td>
<td>Pill identification test (PIT)</td>
</tr>
</tbody>
</table>

a) Direct observation therapy (DOT)

The DOT method requires that the health-care workers directly administer medicines to patients. This method confirms adherence since the health-care worker observes the patient taking the medicine [39]. This method has been successively used in treating tuberculosis (TB). However, this method cannot be used to assess patient adherence to ART in HIV care
centers due to issues of stigma, confidentiality, identification and the huge cost that will be required for the administering of DOT in such lifelong therapy [40].

b) Patients' self-reports

It is the most usual, feasible, and less expensive method to assess ART adherence. In addition, it has an advantage of easy data collection, and it also help to determine why patients are non-adherence [41]. Patient self-report of taking doses accurately during the past 3 days or the past week is the most practical and readily available tool for the assessment of a patient’s adherence in the clinical setting and perhaps the most accurate as only that individual can report his/her actual behavior [42]. Abbreviated forms of questionnaires can be used, even in busy clinics, to quickly assess adherence [43]. Although some patients tend to overestimate their adherence in self report, several literatures have shown that this measure is associated with viral load response [44]. Nevertheless, this method has been criticized for methodological reasons such as reliability, recall bias, social desirability, question style, or the time setting in which the question is asked [45].

c) Pill Counts

It is an objective means of evaluating medicine adherence. It involves physical counting of patient remaining pills by physician, nurse or other health-care practitioner. Pill count adherence is usually calculated by counting the remaining doses of medication and assuming that the remaining pills in excess of what is expected to represent missed doses [46]. Adherence assessed by pill counts correlates better with adherence measured from electronic bottle caps than self-reported dose adherence [47]. However, it has some limitation: when patients remove pills from their containers but do not take them, (i.e. "pill dumping") it leads to overestimation of adherence. In addition, this method does not provide information on other aspects of taking medication, such as dose timing and drug holidays which are important in determining the clinical outcome [48].
**d) Pharmacy Refill Data**

Pharmacy refill adherence has become an increasingly important measure of adherence to antiretroviral medications [49]. It can serve as an adherence measure by providing the dates on which antiretroviral medications were dispensed. In the event that refills are not obtained in a timely fashion, it is assumed that the patient is not taking medication between refills or is missing doses. It offers a simple, inexpensive, and valid method for measuring adherence [50].

**e) Biological Markers**

In this method, adherence is monitored by adding secondary non-toxic medicines to indicate the active primary medicine was taken. This has also some challenges like cost involved in its large scale implementation of all classes of ARV [31].

**f) Therapeutic drug monitoring (TDM)**

TDM involves measuring drug levels in the blood. The ART TDM is useful for the evaluation of non-adherence, multiple drug-food and drug-drug interaction and treatment failure in the absence of viral resistance and non-adherence to medication. TDM is not used routinely to measure adherence because its use is limited to the protease inhibitor classes and also due to cost [33].

**g) Medication Event Monitoring System (MEMS)**

MEMS contain an electronic chip fitted to pill containers which records the removal of the cap. The chip records the date and time of each opening and closing of the medication bottle. Interpretation of these data assumes that a single dose is taken each time the bottle is opened. It is increasingly being used in resource-limited setting and is reliable in recording dosing histories of patients [33]. The advantage of this method is that it correlates well with virology outcome and data are available in computer accessible format. Limitation of MEMS include
patients opening the bottle but not taking the pill, patients decanting pills, being unavailable for blister packs, measuring only one medication at a time and cost [31].

**h) Visual analogue scale (VAS)**

It is an inexpensive and valid method of assessing medication adherence. It tries to measure a characteristic or attitude that is believed to range across a continuum of values and cannot easily be measured directly. For the measurement of adherence, patients are asked to rate their adherence somewhere along the line from 0 to 10 that best guesses their adherence to the prescribed ART in the past 3 or 4 weeks. It has the potential for use in resource limited setting [31].

**i) Pill identification test (PIT)**

PIT involves asking the patients to identify the ART pills (they had been prescribed) with “twin pills” that are similar appearing but not identical. PIT is more reliable at the initial phase of treatment and its validity can be correlated with valid self-report adherence measure. On the other hand, it losses the sensitivity in treatment experienced patients [31].
2. STATEMENT OF PURPOSE

Even though the availability of free antiretroviral drugs is increasing, there are still many obstacles that hinder patients to achieve good adherence to antiretroviral therapy. It is estimated that 19% of adult patients are not retained on antiretroviral therapy after 12 months, while for children, 20% are lost after 12 months in poor countries [11]. This will lead to treatment failure and development of drugs resistance mutation not merely at the individual level but consequently at a global level as stated by the WHO “Drug resistance may result in the failure of the immense global and national efforts to provide hope to people living with HIV” [51]. Therefore, it is of necessary to identify and overcome the factors that reduce adherence to antiretroviral therapy for prolonged viral load suppression [41].

In view of the high number of HIV patients taking ART in Kathmandu district and the lack of data surrounding ART adherence in this population, It was necessary to study adherence to ART among HIV-positive population in Kathmandu district and therefore to understand the factors and influencers of adherence to ART.

3. OBJECTIVES

The general objective of this research was to determine the factors that influence adherence to ART among HIV/AIDS patients.

The specific objectives were to:

- Determine the proportion of AIDS patients that adhere to ART.
- Determine socio-demographic and socio-economic factors associated with adherence to ART among HIV/AIDS patients.
4. MATERIALS AND METHODS

4.1 Study area
The Kathmandu district contains six ART centers. This study was conducted at three ART centers located at Sukra Raj Tropical and Infectious disease Hospital (STID), Bir Hospital and Tribhuvan University Teaching Hospital (TUTH) located at Kathmandu district. STID Hospital is the pioneer and largest institution to provide the ART service to HIV patients from all over the country. These hospitals are the main services providers to those who can hardly reach private health institutions and afford the costly services.

4.2 Study period
Study period was from January 2012 to February 2012.

4.3 Study design
Multisite cross-sectional study.

4.4 Sample size
Sample size was calculated using the formula: \( n = \frac{4pq}{L^2} \) [52, 53].
Where; \( p \) = prevalence of ART adherence in Nepal, i.e. 84%, \( L \) = Allowable Error, and \( q=1-p \).
The value of \( (p) \) was taken from a similar study conducted in Nepal previously where the prevalence of adherence was found to be 84% [52]. In the present study, \( (L) \) is chosen to be 5% giving a power of \((1-L) = 95\% \).
Therefore the sample size \((N) = \frac{4pq}{L^2} = 4 \times 0.84 \times (1-0.84)/(0.05 \times 0.84)^2 = 316 \) subjects.

4.5 Inclusion and Exclusion criteria
This study included patients aged 18 years or older who were receiving ART therapy for at least 3 month prior to the study period and were able to give informed consent. Prisoners and patients aged below 18 years old were excluded.
4.6 Study sample

The 316 patients were assessed from the above mentioned three governmental hospitals at Kathmandu district. The three ART centers were selected randomly out of the six centers in the district. The proportion of patients included from each ART center was allocated according to the proportion of patients registered and receiving antiretroviral therapy in each center out of the total number of patients registered and receiving therapy in the three centers combined. Therefore, out of 2240, 102 and 114 patients receiving ART at STID, Bir and TUTH hospitals, respectively, the 316 sample size included 287 (91%), 15 (5%) and 14 (4%) patients from the three hospitals in the same order.

Generally, more than 50 patients used to visit the ART center at STIDH each day, and less number of patients visited the other ART centers. Patients attending outpatient clinics for regular follow-up and to take medicine were approached for interview. Patients were identified with the help of clerks working at the ART centers. They were offered to participate in the study without any incentive.

Eligible patients who were able to give informed consent, were further informed about the purpose, objective and methodology of the study. Then they were interviewed with the help of trained researcher in a private location. Each patient was interviewed for 15-20 minutes. In order to meet the required sample size, the same approach was followed on the patients attending the outpatient clinic during the months of January and February 2012. Pre-ART and ART number of each participant were recorded to prevent any repetition of participants. To avoid information bias, information was obtained only from respondents, and not from health providers.

4.7 Sampling method

Simple random sampling method was used for the research.
4.8 Data collection

The questionnaire (Appendix-1) used in the present study was adapted from an earlier study, with slight modifications, to fit the Nepal’s norm [55]. Validity was ensured by careful selection of important items to be included in the questionnaires. In this process, flow of questions, presence of sensitive questions, and appropriateness of categorization of variables were assessed. The questionnaire was finalized by consulting two HIV/AIDS experts in Kathmandu valley and the study supervisor, and then the questionnaire was translated into Nepali (the major language spoken in the Nepal) and verified by a second translator.

The questionnaire consisted of questions covering socio-demographic information related to ART adherence and questions related to the patient’s basic characteristics and socioeconomic status. In addition, the patient’s medical records were used to collect information about the CD4 cell count and the type of antiretroviral drugs prescribed to them.

The explanatory variables were categorized as follows: age (continuous variable), sex (male/female), education (literate/illiterate), occupation (employed/unemployed), and marital status (unmarried/ever-married), income (tertiles), and time to reach ART center (continuous variable), use of alcohol in the past month (yes/no), and use of illegal drugs in the past six months preceding the interview (yes/no), reminder method used to take pills (yes/no). The clinical characteristics included the latest available CD4 cell count (≤200/>200), duration of antiretroviral treatment (continuous variable), side effects (yes/no), pills burden (continuous variable).

4.9 Assessment of adherence

The main outcome variable in this analysis was measured by asking patients to recall their intake of prescribed doses in the last seven days prior to the interview. In an attempt to minimize recall bias patients were asked about their adherence over the previous day, previous 3 days and previous week. Self-reported adherence to all ART drugs was calculated
as the ratio of the doses taken during specific time-period over the total number of ART doses prescribed to the same time-period. The result were expressed in percentage and those patients reported intake of 95-100% of the prescribed ART without delay of more than one hour in the past one week were considered adherent to ART. Similarly, those patients who reported taking less than 95% of the prescribed pills were considered as non-adherent.

4.10 Statistical analysis

The information collected from the respondents were sorted, coded and entered in datasheet created in Statistical Package for Social Science (SPSS) version 16. Double data entry system was used to minimize errors in data entry. Differences between adherence and non-adherence subjects were tested using t-Student test and Chi-Square test for continuous and categorical explanatory variables, respectively. The strength of association between explanatory variables and adherence was measured using logistic regression and was reported as odds ratio (OR) with 95% confidence interval.

First the association was measured for each explanatory variable in univariate model. Then each univariate model was adjusted for age and sex. In the second step, multivariate analysis was conducted including all the variables in one model. In the last step, only variables with statistical or borderline significant association in the multivariate model (including all variable) were included in the final model. The criterion for statistical significance was $p \leq 0.05$. 
5. ETHICAL CONSIDERATION

Ethical approval was obtained from Nepal Health Research Council (NHRC) (Appendix-3) and National Centre for AIDS and STD Control (NCASC). In addition, permission letters were obtained from the directors of the three hospitals. The participants were informed about the aims, methods, and anticipated benefits of the research and they were also assured of their right to terminate their participation at any time if they feel uncomfortable. Both verbal and written informed consent were taken from each participant of the study. The participants were not pressurized or induced to be a subject of research. Moreover to ensure confidentiality and anonymity, participants in the study were numbered consecutively. These numbers were entered into the form thus all study materials like questionnaire did not contain any personal identification.
6. RESULTS

A total of 329 patients were approached and 316 (96%) agreed to sign the informed consent and to participate in this study. Out of the 316 participants, 64.6% (n=201) were men and 35.4% (n=112) were women.

Adherence to ART

The majority of the participants claimed not to have missed a single dose in the past one week, where 86.7% (n=274) reported perfect/good adherence (≥ 95%) and 13.3% (n=42) of the participants reported missing medications during the previous week (Figure 1). The adherence prevalence in men and women was 84.3% and 91%, respectively (Figure 1).

![Adherence vs Non-Adherence](image)

**Figure 1: Proportions of HIV/AIDS patients according to antiretroviral therapy adherence status**

Patients who reported missing doses in the last week (n=42) were further asked to assess the principal barriers to treatment adherence. The most frequently cited reasons for not taking ART according to the prescribed schedule were “simply forget” and “busy schedule” (Table 3). Around 11% of the participant’s claimed that they were too sick to take prescribed medicine. As a result of stigma, 4.7% respondent missed their doses in order to hide their
status from their family and friends. While, 4.7% patients claimed that they missed their pills due to the side effects.

* Numbers are overlapping (participants could report more than one reason).

At the time of study, all the patients were receiving free ART. Table 2 provides an overview of the ART regimens. Most of the participants (97.4%) were taking the first line standard ART regimens; consists of a combination of 2NRTIs and 1NNRTI (Non/Nucleoside Reverse Transcriptase Inhibitor). Whereas, (AZT, 3tc, NVP) and (AZT, 3tc, EFV) were the two major combination of ART taken by 61% (n=194) and 22.5% (n=71) of participants, respectively. Only 2.5% (n=8) of participants were at second line therapy.

**General characteristics of the participants:**

The mean age was 36.5 years (range 19-56 years), and the majority of the participants were
between 20 and 49 years indicating a reproductive and sexually active sample. The most common mode of infection were heterosexual transmission 76.5% (n=242) and sharing of needle 12% (n=40). While, 6.9% did not know about how they got infected. Minority of individual (3.7%) reported transmission through blood transfusion. Most of the participants (56.6% (n=179)) were from outside the Kathmandu valley. Only 18% (n=56) of the participants were illiterate. The majority of the participants were employed (76.5 %), and most of them were farmer. Nevertheless, the levels of poverty were high; median monthly family income of the participants was 6668 Nepalese rupees (NRs) = (75.4US$), which is below the annual per capita income of Nepali (750 US$) [56]. Alcohol consumption was reported by 15% (n=48) and illegal drugs use in past 6 months prior to study was reported by 13% (n=43). The mean length of time on ART was 25 months (range 3-61 months). The median CD4 count at start of ART and most recent median CD4 counts were 210 and 299 cells/mm$^3$, respectively. The average length of time to reach the ART center was 2.6 hours (range 1-11 hours) and the average two ways cost to reach ART center was 293NRs. Almost 90% of patients had reported using some kind of medication reminder method to take the medicine at the correct time. Widely used reminder methods were mobile alarm, watch and support from some of the family members. Almost all the patients interviewed were satisfied with their treatment, but many patients had difficulties to come every month to refill ART at ART centers.

Table 5 shows the general characteristics of the study sample by adherence status. Only time to reach the ART center ($p<0.001$), alcohol use ($p=0.026$), illegal drug use ($p=0.017$), side effects ($p=0.005$) and use of reminder method ($p<0.001$) were significantly different by adherence status. Among the participants who took less than 60 minutes to reach the ART center, the prevalence of non-adherence was 7 % whereas out of those who took more than 60 minutes, 21 % of them were non-adherent to ART. Among the non-alcohol users, only 11%
participants were non-adherent to ART whereas 25% were non-adherent among alcohol users. Similarly, among the illegal drugs users, 37.5% were non-adherent to ART whereas only 9.6% were non-adherent among non-drugs users. Among the participants who did not experience side effects, only 3% were non-adherent to ART whereas for the participants who experienced side effects, 16.2% were non-adherent to ART. Among the participants who used reminder methods to take the pills, 89% were adherent to ART, whereas 41.1% of the participants who did not use such methods were non-adherent to ART.

* Row percentage

<sup>a</sup> Traveling cost: cost to reach ART center.

<sup>b</sup> Time: Total time to reach ART center.

<sup>c</sup> Reminder method: using of any reminder tool to take ART.

<sup>d</sup> Alcohol use: Alcohol use in past 1 month.

<sup>e</sup> Illegal drugs use: Illegal drugs use in past 6 month prior to study.

<sup>f</sup> CD4 count: Latest available CD4 cell count.

<sup>g</sup> Tablets daily: Numbers of Tablets taken per day.

Table 6 presents the characteristics of study population stratified by gender. Only, time to reach ART center, history of illegal drugs use in the past 6 month, not using of reminder methods were significantly different by adherence status among both genders. While, alcohol use and side effects were only significantly different among men. Among the past alcohol user the prevalence of non-adherence to ART was doubled for men (31.1%) compared to women (15.8%). Among the past illegal drugs users the prevalence of non-adherence was 40% in men and 30% in women. The prevalence of non-adherence among men who had
experienced side effects was almost double (19.9%) compared to women (9.8 %). Among those who used reminder methods to take the ART, the prevalence of adherence was 87.2 % in men and 94.1% in women.

*The table continues on the next page.*
A total of 248 (78.5%) participants reported experiencing side effect with their medication in the past months. However, only 4.7% of them considered the side effects as barrier to ART adherence. Different side effects reported by participants are shown in Table 7.

* Number are overlapping (participants could report more than one reasons)
The most commonly reported side effects were skin itching (22.8%); headache (13.6%); dizziness (12.7%). These side effects were significantly more reported among non-adherent patients (p<0.005).

Eight participants reported that they stopped taking the ART at least once since they began the treatment. Different reasons given for stopping their ART are shown in Table 8.

**Predictors of antiretroviral therapy non-adherence**

Table 9 presents the crude and adjusted odds ratios of non-adherence by different predictors.

In univariate analysis, non-adherence was significantly associated with the time taken to reach the ART center, past alcohol use, past illegal drugs use, side effects, lowest tertile of traveling cost to ART center and no use of reminder methods. A borderline association was observed with age.

After, controlling (adjusting) for age and sex the same variables as in univariate analysis were significantly associated with non-adherence (p<0.05) and the adjusted odds ratio were almost unchanged; lowest quartile of traveling cost to ART center (OR 0.33 95% CI 0.14-0.82), time taken to reach the ART center (OR 1.39; 95% CI 1.16-1.67), alcohol use in past one month (OR 2.76; 95% CI 1.27-5.96), past use of illegal drugs (OR 5.29; 95% CI 2.49-11.24), side effect (OR 6.99; 95% CI 1.63-29.98), and use of reminder methods (OR 6.04; 95% CI 2.59-14.09) (Table 9).

</table>
When compared by gender, it is interesting that in contrast to women, men with a history of alcohol use in past month (OR 2.9; CI 1.20-7.31) and those who experienced side effects of ART (OR 11.65; CI 1.54-87.5) have shown statistical significant association with non-adherence. In other words, male respondents who had history of alcohol use in the past one month were 2.9 times more likely to report non-adherence than those who didn’t report alcohol use. Similarly, the odds of non-adherence in men who experienced side effects in the past months increased by 1065% compared to men who didn’t experience any side effect.

In multivariate analysis including all the variables listed in Table 9; only, age (p=0.025), sex (p=0.029), time taken to reach the ART center (p=0.055), history of past drug use (p= 0.003), side effects, (p=0.012) and no use of reminder method (p=0.018) were independently associated with non-adherence. A borderline association was observed with the alcohol use in past one month and non-adherence (p=0.092).

The final model included age, sex, time taken to reach ART center, past illegal drugs use, past alcohol use, side effects, and use of reminder tools (Table 10). Negative trends for medication adherence were seen for advancing age. Increment in age by one year increased the risk of non-adherence by 4% (OR 1.04; 95% CI 1.00-1.09). Increase of the traveling time to ART center by one hour was associated with 38% increase in the risk of being non-adherent (OR 1.38; 95% CI 1.12-1.71). The upper limit of the confidence interval for this odds ratio shows that this increased odd could be as much as 71%.

There was no interaction effect seen between the use of alcohol and illegal drugs. However, in the final model, although the odds of non-adherence was more than double in patients with history of alcohol use, the association did not reach a statistically significant level (OR 2.26; 95% CI 0.93-5.44). On the other hand, patients with history of illegal drugs use had almost 4 times the odds of being non-adherent than patients without history of illegal drugs use (OR 3.98; 95% CI 1.71-9.24). The odds of non-adherence increased 388% in patients who had side
effects (OR 4.88; 95% CI 1.09-21.8). Patients who had used reminder tools to take the medication were 3.45 times more likely to adhere to ART compared to those who did not use any reminder tools (OR 3.45; 95% CI 1.33-8.91).

7. DISCUSSION

The overall self-reported adherence rate for one week was 86.7%. The results show that factors such as age, time taken to reach ART center, past drug use, side effects and not using reminder tools are independently associated with non-adherence.

The main reasons accounted for non-adherence were patients simply forgetting to take ART and having a busy schedule and this finding correlates with the finding of other studies [53,54,57,58]. In fact, due to variation in measurement methods of adherence, it is difficult to compare findings from different studies. However, the literature shows that the developing countries have better adherence rates than developed countries. For example, countries like Uganda (89%), Kenya (82%) showed better adherence rates [44,57]. On the contrary, countries like the United States (50%), France (29.1%), and Brazil (63.1%) have lower adherence rates [42].

In this study the level of adherence to antiretroviral therapy, is slightly higher, and consistent to other similar studies in Nepal and compatible to several other studies conducted in developing countries which were also based on self-reported adherence [54,59,60,61]. The possible explanation for getting higher adherence in this study might be due to using self-reported adherence, only assessing the adherence of one week and selecting participants through out-patient department/clinic (OPD) which may have resulted in the participation of only active people. However, results of this study are unique because to my knowledge, this is the first study to assess the factors associated with adherence to ART among HIV patients in Kathmandu district and the first to examine adherence among patients who are receiving free ART services at government hospitals.
Determinants of ART adherence

a) Gender

The proportion of men in this study was approximately two-fold that of women and is similar to the proportion of HIV& AIDS reported in Nepal [23]. The higher number of male respondents might be due to women being far less likely to come forward for treatment. In the univariate analysis, male gender was associated with non-adherence to ART. This might be related to the limitation of cross-sectional-study. However, in multivariate analysis gender was not a significant predictor of adherence. The finding is in agreement with studies elsewhere [52,57,61] but in contrast with the finding of Wasti et al in Nepal [54]. In that mixed method study, it has been reported that the HIV infected women are less likely to adhere to ART, more prone to discrimination by others and tend to be more highly stigmatized than men. Furthermore, in most of the developing countries, the HIV positive women pose a number of challenges regarding social barriers, psychological, epidemiologic, economic and biological aspects, which impact their ability to take medication. So, the challenge to improve access and adherence to ART in women remains critical in most of developing countries.

b) Age

This study shows that ART adherence varied significantly by age. Increase in age by one year increases the risk of being non-adherent by 4%. Increased risk of non-adherent with increasing age might be due to alternation in life style and having a busy schedule with increase in age. This finding contrasts with the American study by Barclay et al showing the patients aged less than 50 years were 2 times more likely to non-adhere [62] and differs from some studies showing no association between age and adherence [54,59,58]. Such variation in results could be due to differences between studies in terms of sampling population. Generally, due to antiretroviral therapy, the number of persons aged 50 years and older living
with HIV & AIDS is increasing [63]. Therefore, further studies on risk associated with old age are needed.

c) Traveling cost and Time

Significant interaction between traveling cost and time taken to reach ART center was found. While traveling cost showed non-significant association in the multivariate model, time continued to have significant independent association with non-adherence; the odds non-adherence increased by 40% for each one extra hour taken to reach ART center. This could imply that the effect of traveling cost is explained within the time taken to reach the ART center. Moreover, the latter could also embrace other daily activities affecting the patients’ plans or priorities according to time available every day. In addition, few patients cited stopping the medicine in past due to the various cost associated with treatment. Overall, the results of this study provide evidence that lack of access due to time to reach ART center can hinder the improvement of adherence among ART patients in resource-limited countries. In accordance to this, two Indian studies [53, 61] and two African studies [57,58] showed that travelling from distant places to ART centres was one of the barriers for adherence to ART. It is unfortunate that, despite extension of ART centers in different regions, PLWH were unwilling to seek treatments at the nearest health institution because of fear of stigmatization [59]. In such situation, patients may have to travel long distances to seek ART services where time could be a problem. In Nepal, traveling long distances to receive treatment was common, and not surprisingly, transportation difficulties were often reported to be a major hindrance to adherence [60].

d) Side effects

This study shows that patients’ experience of medical side effects predicted non-adherence. Side effects such as dizziness, skin rash, vomiting were more frequently reported. The odds of adherence among those who didn’t experience side effects was 4.88 times higher than those
who reported experiencing medication side effects. This finding was consistent with findings of several other studies [54,58,59,64]. In addition, one Meta-analysis showed that varying from mild to severe and from acute to chronic, side effects and toxicity of the complex ART drugs was an important reason for non-adherence [65]. However, one Kenyan study showed that adverse side effects doesn’t significantly influence non-adherence [57]. So it is important to educate and counsel patients on how to cope with these side effects. As mentioned in systematic review by wasti et al “Trust in ART medication, self-awareness of one’s health and knowledge of the consequences of adherence and non-adherence are an important basis for trust and belief that can reinforce adherence despite side effect” [60]. Symptoms management is a vital part of successful adherence to ART. Hence, it is necessary to discuss all potential side effects with the patients before they begin the medications to prevent feelings of premeditated non-disclosure. Moreover, each patient must be assessed individually for readiness to adhere to a complex medication regimen [33].

e) Illegal drugs use

Both illegal drugs use and alcohol use were associated with non-adherence in univariate analysis and illegal drugs use remained the strongest predictor for non-adherence in multivariate analysis. Among men, only alcohol use was associated with worse adherence. Alcohol use was not associated with worsened adherence in women in final multivariate model. This result shows that alcohol use may disproportionately impact antiretroviral adherence in men. In a Meta analysis, alcohol use was associated with 40% to 50% reduction of adherence [65]. Therefore, more focused interventions for enhancing adherence are needed among alcohol user men. Similarly, the odds of non-adherence among those who had past history of illegal drugs use was 4 times higher than those who did not report history of past illegal drugs use. This finding was in agreement with other studies [60,66,67,68]. Other studies showed that patients with history of substance use were significantly less engaged
with their health care provider and such patients are likely to exhibit higher rate of refusal to treatment [32,65]. Furthermore, neurological and psychological problems can yet be additional factors related to non-adherence among illegal drug users.

f) Reminder tools use

Both univariate and multivariate analysis in this study confirmed that having a reminder tool is a strong predictor of adherence. This finding is supported by Wang et al who found that the risk of non-adherence among patients with no reminder tool was 4.2 times greater than for those who employed some reminder method [29]. Edward et al. in a review on adherence of ART in developing and developed countries showed that support from friends and family as reminders facilitates successful adherence to ART [69]. In addition, disclosing one’s ART status to others had positive influence on adherence [60,65].

Although, many other potential predictors were included in this study, they did not show consistent associations with the adherence of ART.

The number of pills taken per day was not associated with the adherence in both univariate and multivariate analysis. However, several other studies have shown that adherence decreases with increase in the number of tablets and number of daily doses [42,61]. One Indian cohort study showed that medication adherence increased by 100% in those on less than 5 tablets per day [61]. In contrast to this, various studies reported that despite having the new regimens - fewer tablets and daily doses-, adherence still remains a problem [28,42]. Due to the small sample size of this cross-sectional study and the adherence assessment over a short period of time, it is difficult to reach valid conclusions on whether the number of tablet per day is associated with ART adherence or not. Thus, other objective tools such as pill count, electronic pill caps, and other biological methods should be included in future studies.

Interestingly, no significant associations were found between levels of education and income and adherence. This is in accordance to other studies on adherence in Nepal where the
reported income and education level did not significantly influence non-adherence. [54,59]
Similarly, marital status did not significantly influence adherence in this study. This finding is
inconsistent with the findings of Byakika et al in Uganda. [70] In relation to the time elapse
since the start of the antiretroviral treatment, in this study being on ART for less than 2 year
or more than 2 year was not associated with non-adherence. This differs from literature,
which was consistent with finding of other several studies [42,53,58] but this is in contrast
with the finding of Indian cohort study by Cauld beck et al. [61] who found that duration of
treatment for less than 6 months or greater than 10 years was associated with the largest
number of missed doses.

8. Strength and Limitation
The cross-sectional design made it faster, cheaper and easier to perform the study. In order to
ensure the validity, a questionnaire used earlier in a study in Togo was used. Additionally, in
order to ascertain the level of understanding of questionnaires, a small pilot test was
conducted among few HIV& AIDS patients. Patients were interviewed from ART centers at
three government hospitals so they can be considered as a representative of HIV& AIDS
patients in Nepal. Also, the sample size in this study is higher than previous similar studies
conducted in Nepal. In order to minimize the selection bias, all patients coming to out-patients
department in the month of January and February were approached for interview and the
response rate was high. Adherence was assessed only for one week prior to the study so that
patients can accurately recall their behavior minimizing the chances of recall bias.
Furthermore, multivariate modeling was used to assess the factor associated with adherence.
Despite the numerous strengths, this study has some limitations. Adherence was assessed only
in terms of missing doses. Other dimensions of adherence such as whether patients took
medicine in accordance to time and dietary instructions were not interviewed. Although,
selection bias is limited in this study, it should be mentioned that only patients who personally collected/refilled their treatment from the ART centers were included and no approach was made to patients having their ART delivered at home by volunteers. On the other hand, there might be other confounding factors that were not measured and adjusted for in this study, and the patients’ self-reports might have been touched by the social desirability effect. Furthermore, this study is cross-sectional; therefore, the temporal relationship among variables studied is unknown, thus the causal relation cannot be established.
9. CONCLUSION

Prevalence of adherence found in this study seems to be encouraging. The finding suggests that male gender, age, time taken to reach ART center, side effects and substance use present additional barrier for adherence to ART. Whereas having reminder tools to take the pills enhanced adherence. Nevertheless, even within the context where free ART service is provided to HIV patients, time taken to reach the ART center remains an important barrier to access and adherence to HIV patients. Moreover, current finding demonstrates that in spite of universal access to ART, achieving perfect adherence remains a challenge with HIV& AIDS and non-adherence remains a barrier to combat the epidemic. In order to improve adherence among HIV patients, NCASC should provide equitable access to its services regardless of gender or socioeconomic status of the patients. Adherence to ART varies over time and between individuals. Therefore using multiple measures, further longitudinal research including both public and private services delivery sites are needs to assess to determine the factors associated with adherence.
10. RECOMMENDATIONS

- Addressing non-adherence to ART in developing countries like Nepal may require different solution from those in developed countries, where access to ART is not a major concern.

- In an effort to remove obstacles to treatment adherence, health care providers should give clear instructions and proper counseling to patients focusing on managing side effects. Besides that, prescribing greatly simplified ART regimen that has low incidence and severity of adverse effects can improve adherence.

- To improve adherence it is important to empower patients by providing skills to take medicines in public places, where they might have to hide to take medicine due to other socio-cultural obligation. In addition, governments should encourage a supportive environment where PLWHs do not have to worry about stigma and discrimination.

- Maintaining morning and evening OPDs or keeping ART centre staff on shift duties can help the patients to better manage their time. In this case, patients can manage time to come to ART center despite having busy schedule.

- Different electronic reminder devices such as watch, mobile, pillboxes with alarms should be widely developed as a part of the set of HIV treatment adherence tools.

- Patients reporting a history of illicit drug use should be targeted to enhance adherence to ART.

- To encourage patients to adhere to their medication, community support such as Community Care Centers (CCCs), Comprehensive care center and home-based care need to expand at village or districts/regions which have high levels of PLWH.

**INFORMED CONSENT**

Hello. My name is Rajesh Shigdel and I am Masters Student of Public health. I am conducting a survey about adherence of ART. I will appreciate your participation in this survey. The information you provide will help to know the factor affecting the Adherence to ART and help to plan health services. The survey usually takes between 10 and 20 minutes to complete. Whatever information you provide will be kept strictly confidential and will not be shown to other persons.

Participation in this survey is voluntary and you can choose not to answer any individual question or all of the questions. However, I hope that you will participate in this survey since your views are important.

At this time, do you want to ask me anything about the survey?

Are you willing to participate in the study?

1. Yes  
2. No

Signature.................
Questionnaire for assessing adherence level to antiretroviral therapy among HIV/AIDS patients:

I. Socio-demographic characteristics

1. Age: ........
2. Sex: 1= male 2= female 3 = Third gender
6. What education do you have?
   5. Office worker 6. Others......
8. Place of residence: 1. Inside Kathmandu Valley 2. Outside Kathmandu valley
10. Monthly family income .................
12. Cost of traveling to ART center? .................
13. Time to reach at ART Center: ............. Minutes
14. How were you infected with HIV?
   1. Heterosexual intercourse (Vaginal Intercourse)… 2. Homosexual intercourse (anal intercourse) .......
   5. Other............. 6. Don’t know
15. When have you been diagnosed as positive for HIV? Month /___/___/ Year /___/___/___/___/
16. When did you start on the ART? Month /___/___/ Year /___/___/___/___/

II. Knowledge of the treatment

17. Do you know the role of ART? 1=Yes 2=No
18. Is it a combination treatment? 1=Yes 2=No

Would you give me some information about the medicament you are taking?
19. Do you know the ART’s medicine prescribed to you? 1=Yes 2=No
20. Type of antiretroviral medicine prescribed to you: .................

REMARK: Taking according to the meal:
1=Before 2=During 3=After 4= No particular recommendation
21. Do you have own method to remember time and recommendation to take your medicine?
   1= Yes 2=No
22. If yes, which one? 1= Watch … 2=one of my family’s member ........ 3=other........

III. ADHERENCE OF THE TREATMENT
23. During the last seven (07) Days have you missed to take your medicament?  1=Yes  2=No
24. How many time(s)? ...........
25. How many tablets are not taken? ...........
26. How many tablets were prescribed per day? ...........
27. Have you at least once got some information (advices) about the consequences of a bad using of your treatment?  Yes / No
28. If yes, from whom?  1= Consultant/ (Adviser)  2= Doctor  3= Parents  4=Friends

IV. FACTORS OF POOR ADHERENCE

29. Is there any reason behind that you are not taking medicine regularly?  Yes / No
If yes: then can you mention the reason ............

V. SIDE EFFECTS

30. Have you any undesirable or sides effects during your treatment?  1=Yes  2=No
If yes, what are those side effect ..............
31. Have you ever stopped or changed the medicaments?  1=Yes  2=No
32. If yes, Why? You can tick more than one answer.
1. Inefficiency treatment ...  2. sides effects...  3. financial difficulty......
4. I didn’t want to continue treatment ....  5. Lack of drugs at ART canter....  6. Others ........
33. Alcohol use in past month:
1. Never.  2. Once a month.  3. 2–3 times a month.  4. once/twice a week.
5. 2–3 times a week.  6. Nearly every day.
34. Illegal drugs use?  Never......  Past use ......  Daily ......  Occasional ......
If yes, then have you taken illegal drugs during last six month?  Yes  No
36. Have you ever injected drugs?  yes  no
37. If yes, do you currently inject drugs?  yes  no

VI. Prescription of the treatment

38. Are you satisfied with your treatment?  1=Yes  2=No
39. If No Why? ..................................................

Data from the medical register

40. CD4 cell count ............... (Cells/mm3)
41. Type of antiretroviral medication .............

Thank you for taking the time to complete the questionnaire and support this research.

To whom it may concern

I hereby confirm that Rajesh Shigdel, born 24.6.1986, is a master student at the University of Tromsø, Norway. The protocol for his Master Thesis project, titled "Factors associated with Adherence to Antiretroviral Therapy in HIV-infected Patients: A cross-sectional study in Kathmandu Valley" has been approved by me, as his main supervisor.

He is advised to apply for ethical approval of his study in Nepal.

Sincerely,

Elise Klouman

Mr. Rajesh Shigdel
Principal investigator
University of Tromsø, Norway

Ref: Approval of Research Proposal entitled Factor associated with adherence to antiretroviral medication in HIV-infected patients: A cross-sectional study in Kathmandu District

Dear Mr. Shigdel,

It is my pleasure to inform you that the above-mentioned proposal submitted on 2 February 2012 (Reg. no. 1/2012 please use this Reg. No. during further correspondence) has been approved by NHRC Ethical Review Board on 2 April 2012 (04/02/12-20).

As per NHRC rules and regulations, the investigator has to strictly follow the protocol stipulated in the proposal. Any change in objective(s), problem statement, research question or hypothesis, methodology, implementation procedure, data management and budget that may be necessary in course of the implementation of the research proposal can only be made so and implemented after prior approval from this council. Thus, it is compulsory to submit the detail of such changes intended or desired with justification prior to actual change in the protocol.

If the researcher requires transfer of the bio samples to other countries, the investigator should apply to the NHRC for the permission.

Further, the researchers are directed to strictly abide by the National Ethical Guidelines published by NHRC during the implementation of their research proposal and submit progress report and full or summary report upon completion.

As per your research proposal, total research amount is NPR. 2,812,000.00 and NHRC processing fee is US$ 100.00.

If you have any questions, please contact the research section of NHRC.

Thanking you.

Sincerely Yours,

Appendix 6: Permission Letter for Fieldwork (Bir Hospital)

Date: 2018-06-20

To: Shre煎essa Shryel
University of Tromso, Norway.

Subject: Permission for Fieldwork

This letter is to formally authorize you to conduct your fieldwork at Bir Hospital, with the following conditions:

1. You are permitted to conduct your fieldwork at Bir Hospital from 2018-01-12 to 2018-07-12.
2. Your fieldwork will be focused on the ART Clinic and HIV services provided there.
3. You will be supervised by Dr. Shyam Shankar Shrestha, Head of the ART Clinic.

Kind regards,

Re: Permission of Information collection

Dear Sir/ Madam,

In reference to the letter of National Centre for AIDS and STD Control (NCASC), ref no-329, letter no-2012, Mr. Rajesh Shigdel has been provided permission dated from 22nd of January 2012 for his research work during his MPH study, to collect information through PLHIV client attending in collaborative ART centre of this Hospital.

The ART centre is established in February 2004 which is one of the largest centres in Nepal. In 2009, an international NGO, AIDS Healthcare Foundation (AHF Nepal) joined to support the ART centre thus it has been functionally called as collaborative ART centre.

I wish all the best in his academic excellence.

Sincerely,
