SUMMARY

Healthcare workers (HCWs) may be a reservoir for *Staphylococcus aureus* transmission to patients. We examined whether HCW status is associated with *S. aureus* nasal carriage and population structure (*spa* types) in 1302 women (334 HCWs) and 977 men (71 HCWs) aged 30–69 years participating in the population-based Tromsø Study in 2007–2008. Multivariable logistic regression models were used. While no methicillin-resistant *S. aureus* (MRSA) was isolated, overall, 26·2% of HCWs and 26·0% of non-HCWs were *S. aureus* nasal carriers. For women overall and women residing with children, the odds ratios for nasal carriage were 1·54 [95% confidence interval (CI) 1·09–2·19] and 1·86 (95% CI 1·14–3·04), respectively, in HCWs compared to non-HCWs. Moreover, HCWs vs. non-HCWs had a 2·17 and 3·16 times higher risk of *spa* types t012 and t015, respectively. This supports the view that HCWs have an increased risk of *S. aureus* nasal carriage depending on gender, family status and *spa* type.

Key words: Healthcare worker, infection control, population-based, residing with children, *Staphylococcus aureus* nasal carriage.

INTRODUCTION

Staphylococcus aureus and its resistant form, methicillin-resistant *S. aureus* (MRSA), rank top among the clinically most relevant nosocomial pathogens, leading to increased morbidity, mortality, length of hospital stay and costs [1–4]. Colonized healthcare workers (HCWs) are capable of developing clinical *S. aureus* infections [5, 6], transmitting *S. aureus* to

patients [6–8], and introducing *S. aureus* into their families [9–11]. Understanding *S. aureus* colonization patterns in HCWs may aid in the development and reinforcement of infection control strategies and add to the understanding of *S. aureus* epidemiology.

Interestingly, recent reports have revealed higher *S. aureus* nasal carriage rates in surgeons than in high-risk patient groups [12] and more frequent MRSA nasal carriage in nurses than other HCWs [13, 14], supporting the view that healthcare service may be a risk factor for carriage. However, studies in the healthcare setting generally lack a broader perspective on the ecological context of HCWs in the community

and how background prevalence in the general population and households may bias the results. Importantly, *S. aureus* nasal carriers may 'impose' their carrier status upon other household members [10, 11, 15], and the bacterium can be reintroduced into the hospital by intrafamilial spread from and to HCWs [9, 11]. Moreover, with novel technologies for molecular typing of *S. aureus* there are better opportunities for detailed epidemiological studies [9].

In The Tromsø Staph and Skin Study (TSSS), including 4026 adults aged 30–87 years, participating in a population-based health screening survey, we recently reported overall nasal carriage rates of 35% in men and 20% in women [16], and a heterogeneous distribution of *S. aureus spa* types by gender and age [17]. Importantly, we found overlapping population structures for *S. aureus* nasal isolates in this population-based screening and clinical *S. aureus* isolates in septic patients from the same geographical area and time period [17]. TSSS was designed to study the host–microbe–environment relationships in *S. aureus* carriage within an unselected general population, focusing on healthcare-associated environmental risk factors (i.e. hospital stay, work in healthcare services) reported at the screening. Thus, to explore *S. aureus* epidemiology in HCWs, we compared screening data on *S. aureus* nasal carriage, *spa* types and residing with children, for HCWs and non-HCWs from the working-age population, 30–69 years, participating in TSSS.

METHODS

Population and study design

The study subjects in TSSS were men and women who participated in the sixth survey of the Tromsø Study (Tromsø 6) conducted in 2007–2008. The Tromsø Study is an ongoing population-based cohort study with five previous surveys undertaken between 1974 and 2001 [18]. Based on the official population registry, residents of the municipality of Tromsø were invited to take part in the survey. In Tromsø 6 all subjects aged 40–42 and 60–87 years, a 40% random sample aged 43–59 years, and a 10% random sample aged 30–39 years were invited. In addition to the random samples, 295 participants were invited because they attended the second visit in the fourth survey in 1994. Invitation letters were sent randomly, avoiding selection bias during the sampling period. A total of 12984 men and women aged 30–87 years

attended Tromsø 6 (attendance rate 65.7%). Due to lack of capacity and funding, young adult residents (aged 18–29 years) could not be invited [18].

For the study of *S. aureus* nasal carriage in a general population, we considered a more evenly distributed sampling across age groups to be most suitable and the inclusion of 4000 observations to be sufficient for analysis of host–microbe–environment relationships. Thus, in Tromsø 6, during October 2007–June 2008, all attendees aged 30–49 years ($n=1730$) and random samples of older attendees aged 50–87 years ($n=2629$, relative distribution of birth cohorts as in the municipality) were asked to participate in TSSS, including a nasal swab culture at the screening (first visit) and a repeated nasal swab culture at a second visit within a few weeks [16]. A total of 4026 men and women aged 30–87 years (30–49 years, $n=1597$, $\text{age}_{\text{mean}}=41.1$, $\text{age}_{\text{median}}=41$; 50–87 years, $n=2429$, $\text{age}_{\text{mean}}=62.6$, $\text{age}_{\text{median}}=61$) had at least one nasal swab culture taken and were included in TSSS, and of these, 2997 subjects (30–49 years, $n=1118$, $\text{age}_{\text{mean}}=41.1$, $\text{age}_{\text{median}}=41$; 50–87 years, $n=1879$, $\text{age}_{\text{mean}}=62.4$, $\text{age}_{\text{median}}=61$) had a repeated culture taken (Fig. 1). Mean interval between cultures was 33 days and for 90% of the observations the interval was >12 days.

For the present study of *S. aureus* epidemiology in HCWs, 37 subjects who had taken antibiotics within 24 h of the first or second visit, were excluded. According to the working age in Norway, 373 subjects aged ≥ 70 years were excluded. The age of retirement in Norway is normally from 67 years, but may be postponed until age 70 years. In 2008, 22% of men and 14% of women aged 67–69 years were registered in the Norwegian labour force [19]. Of the remaining subjects aged <70 years, a total of 217 (30–49 years, $n=116$, $\text{age}_{\text{mean}}=40.9$, $\text{age}_{\text{median}}=41$; 50–69 years, $n=101$, $\text{age}_{\text{mean}}=59.7$, $\text{age}_{\text{median}}=59$) with missing data on HCW status were excluded. Thus, for the present analysis 2279 participants aged 30–69 years (30–49 years, $n=961$, $\text{age}_{\text{mean}}=41.1$, $\text{age}_{\text{median}}=41$; 50–69 years, $n=1318$, $\text{age}_{\text{mean}}=58.7$, $\text{age}_{\text{median}}=59$) were included (Fig. 1).

The study was approved by the Regional Committee for Medical and Health Research Ethics, North Norway, and all attendees signed an informed consent form. Interviews and clinical examinations were performed at the screening centre by specially trained technicians according to standardized procedures. Body height and weight were measured, and body mass index (BMI) calculated (kg/m^2) [18]. Two

self-administered structured questionnaires covered a broad range of issues related to health and lifestyle, including the question ‘Are you residing with children aged <18 years?’ (yes/no), referred to as ‘residing with children’ in the present analysis.

Assessment of HCW status

Self-reported information on current healthcare-associated environmental exposure was obtained by the interview question ‘Do you work in healthcare services?’(yes/no), asked at the second visit. Healthcare services were defined as hospital, nursing home, senior care service, general practitioner (GP)’s office,

and public health centre. The large-scale setting with multiple screening items in Tromsø 6 allowed for only one screening question on workplace. As an open interview question on workplace (all kinds of professions) turned out to be too time-consuming during the initial 4 weeks of the survey, it was decided to narrow it down to the specific question on work in healthcare services. This change in data collection led to missing information on HCW status until the fifth week of the survey. Thus, for the present study only the data collected after the inclusion of the specific question on work in healthcare services were analysed. The majority of HCWs in Tromsø work at the University Hospital of North Norway (UNN). UNN has about

4400 employees and is the only hospital within a radius of >200 km.

Detection of *S. aureus* nasal carriage

Both vestibuli nasi were sampled by the same NaCl-moistened sterile rayon-tipped swab and placed in Amies charcoal transport medium (Copan, Italy). Within 3 days, all specimens were cultured at UNN, using blood agar (Oxoid, UK), chromID™ *S. aureus*, and chromID™ MRSA agar plates (bioMérieux, France). In order to ensure high sensitivity, all culture plates were incubated for 42–48 h at 37 °C. To retain high specificity, colony morphology was thoroughly examined and the most dominating suspected green colony on the chromID plates was selected for further confirmation as *S. aureus* by the Staphaurex Plus (Remel, USA) agglutination test. All confirmed *S. aureus* isolates were frozen at –70 °C in glycerol-containing liquid media for molecular analysis. No MRSA was isolated [16].

S. aureus carrier status was defined by the results of both nasal swab cultures at the first and second visits; persistent carrier = two positive cultures; non-carrier = one or no positive culture [20]. Our validation in 120 participants in TSSS, showed excellent inter-method reliability for *S. aureus* nasal carrier status using 1-week interval vs. 2–6 weeks between the nasal swab cultures [weighted kappa = 0.85, 95% confidence interval (CI) 0.77–0.92], also implying a low rate of transient colonization [21].

spa typing

S. aureus nasal isolates from the first (99.6%) and second (99.9%) visits were *spa* typed as described elsewhere [17]. Primers recommended by Ridom GmbH (Germany) were used, i.e. spa-1113f and spa-1514r as described previously by Strommenger *et al.* [22]. Polymerase chain reaction (PCR) products were sequenced on both strands by MacroGen Korea or MacroGen Europe and *spa* types were assigned using Ridom StaphType software (Ridom GmbH, Germany) [23].

According to the Ridom StaphType software 264 and 268 different *spa* types were assigned in the first and second visits, respectively. In total, six and seven isolates were not typed due to repeated negative *spa* PCR amplification or deviating repeat length, respectively.

Among *S. aureus* nasal carriers 92.5% (98/106) of HCWs and 93.0% (453/487) of non-HCWs had the

same *spa* type in both samples (data not shown), also in accordance with the literature [24].

Statistical analysis

Logistic regression models stratified by gender were used to estimate odds ratios (ORs) and 95% CIs for *S. aureus* nasal carriage overall and by *spa* types associated with HCW status. The analysis of *spa* types was restricted to the nasal swab cultures of the first visit.

Selected characteristics of HCWs and non-HCWs were compared by two-sided Student's *t* test for continuous variables and two-sided Pearson's χ^2 /Fisher's exact test for categorical variables.

We evaluated model fit and plausibility of several covariates and the final multivariable models included age, BMI, current daily smoking (yes/no), alcohol intake (<2 or \geq 2 times a week), recreational physical activity (three levels), household income (< or \geq €37000/year), education level (< or \geq college/university), and residing with children (yes/no). We tested whether residing with children modified the association between HCW status and *S. aureus* nasal carriage in stratified logistic regression analysis. Testing for interaction was done by inclusion of the multiplicative terms of the two predictor variables in the models. Tests of reliability of the final analyses were done by the Hosmer–Lemeshow goodness-of-fit test.

All tests were two-sided. Stata version 11.0 (StataCorp, USA) was used for statistical analyses.

RESULTS

HCWs comprised 334 (25.7%) of 1302 women and 71 (7.3%) of 977 men. HCWs were younger than non-HCWs in both women and men (both *P* values <0.05) (Table 1). Among women, HCWs were more often residing with children and reported higher household income, education level, and recreational physical activity level, and less frequent alcohol intake than non-HCWs. Among men, HCWs reported more frequent alcohol intake and hospitalization over the last 12 months than non-HCWs (all *P* values <0.05) (Table 1).

Risk of *S. aureus* nasal carriage

The overall prevalence of *S. aureus* nasal carriage was 26.2% in HCWs and 26.0% in non-HCWs. The

corresponding sex-specific rates were 22.5% and 18.4% in women ($P=0.11$), and 43.7% and 34.1% in men ($P=0.10$), respectively (Table 2).

In multivariable analysis, HCW status was not associated with *S. aureus* nasal carriage in the total population (Table 2). However, female HCWs had a 54% increased risk of *S. aureus* nasal carriage vs. non-HCWs (OR 1.54, 95% CI 1.09–2.19), while male HCWs did not differ from non-HCWs with respect to risk of *S. aureus* carriage.

For women residing with children, HCWs had an 86% increased risk of *S. aureus* nasal carriage compared to non-HCWs (multivariable analysis: OR 1.86, 95% CI 1.14–3.04; P for interaction = 0.42) (data not shown), while in women not residing with children there was no difference in risk by HCW status. For men, there was no pattern of effect modification by family status.

Risk of *S. aureus* nasal carriage by *spa* type

At first visit, a total of 61, 41, 32, 26, 22 and 15 participants were colonized with *spa* types t012, t084, t065, t021, t015 and t002, respectively, which were the predominant *spa* types including almost one third of the *S. aureus* nasal isolates. The distribution of the

31 most common (≥ 4 observations) *spa* types in the first sample according to HCW status is shown in Figure 2. The majority of these *spa* types were observed in both HCWs and non-HCWs, while seven *spa* types were restricted to non-HCWs, among these *spa* type t002. None of the most common *spa* types were found in HCWs only.

Among *S. aureus* nasal carriers, HCWs had 2.17 and 3.16 times higher risk of *spa* types t012 and t015 in the first sample, respectively, compared to non-HCWs (multivariable analysis: OR 2.17, 95% CI 1.16–4.08 and OR 3.16, 95% CI 1.13–8.87) (Table 3).

When restricting the analysis to *S. aureus* nasal carriers residing with children, HCWs had a 2.42 times higher risk of *spa* type t012 in the first sample compared to non-HCWs (age- and gender-adjusted analysis: OR 2.42, 95% CI 1.03–5.70). The association for *spa* type t012 was particularly strong in male nasal carriers (age-adjusted analysis: OR 4.61, 95% CI 1.36–15.61) (Table 4). Among *S. aureus* nasal carriers not residing with children, HCWs had a fourfold increased risk of *spa* type t015 in the first sample compared to non-HCWs (age- and gender-adjusted analysis: OR 4.28, 95% CI 0.99–18.43) (Table 4).

DISCUSSION

In this large population-based study with participants aged 30–69 years with repeated nasal swab cultures, working in healthcare services was associated with a 54% increased risk of *S. aureus* nasal carriage in women. The risk was even higher in women residing with children. For men, work in healthcare services and residing with children were associated with increased prevalence of common *spa* types. Our study

suggests that a synergism between environmental risk factors (work and household) is of importance for *S. aureus* carrier status in HCWs.

To our knowledge, this is the first study which reports that female HCWs have a higher risk of *S. aureus* nasal carriage than female non-HCWs in a general working-age population. Interestingly, other studies confined to HCWs, observed higher nasal carriage rates of MRSA in nurses than in other healthcare professionals, and cited increased patient

contact as a cause [13, 14]. Our screening study did not include information about the HCWs' profession. However, the majority of the Norwegian healthcare workforce are nurses and auxiliary nurses, and about 90% of these are women [25, 26]. Thus, our findings suggest that work in healthcare services is an environmental risk factor for *S. aureus* nasal carriage in women, due to a substantial amount of contact with patients and the elderly in residential care when working as nurses and auxiliary nurses. No MRSA was isolated in our study. However, epidemiological evidence supports a similar mechanism for transmission of methicillin-sensitive *S. aureus* (MSSA) and MRSA usually via direct contact with patients and other close contacts (household members, etc.) [27, 28].

We observed that working in healthcare services in combination with residing with children was a high risk cluster for *S. aureus* carriage in women. Our findings are in agreement with current literature supporting the view that contact transmission within HCWs' families may affect the burden of MSSA and MRSA infections in hospitals [9, 11]. Importantly, residing with children *per se* was not associated with *S. aureus* nasal carriage in our study, and number of children aged <18 years and age did not differ between HCWs and non-HCWs (results not shown). Information on childcare was not included in our study, and attending kindergarten has been associated with increased risk of *S. aureus* colonization in children [29]. However, it can be assumed that use of kindergarten was not a major confounder in our

analysis, as there have been places in kindergarten for all children in Tromsø since 2005 [30] and 89.4% of female non-HCWs residing with children were part-time or full-time workers. Thus, we hypothesize that the environmental pressure caused by high rates of contact transmission of *S. aureus* from both patients and children may exceed the ability of female HCWs (i.e. through hand hygiene, immune responses) to defend themselves against colonization.

The population structure of *S. aureus* colonizing HCWs and non-HCWs was similar, as expected from others [13] and our previous comparative study of clinical and nasal carrier *S. aureus* isolates in Tromsø [17]. However, we observed that work in healthcare services was associated with an increased risk of *spa* types t012 and t015, which both ranked in the top five in our study and are also frequent worldwide [31, 32]. Thus, we may expect *spa* types t012 and t015 to be frequent causes of autoinfections in patients in the community and in hospitals, with an increased potential for transmission, that may also partly explain our findings.

Among men, HCW status and residing with children predicted *S. aureus* carriage by *spa* types and not overall carriage rates. Even though there is considerable degree of uncertainty in our estimates, we can hypothesize that in the male human population, common *S. aureus spa* types have specific main niches defined by environmental factors. The female preference of the common *spa* type t012 in our study population, may possibly confound the results in women [17].

The main limitation of our study is the lack of information on profession, workplace and patient contact. The cross-sectional design demands caution in interpretation regarding any causal relationship. Thus, future prospective population-based studies including work and home exposures are needed to improve our knowledge about high-risk groups and environmental targets for more effective prevention of *S. aureus* carriage in HCWs. As the prevalence of *S. aureus* carriage in younger adults is relatively high, particularly in men [33, 34], the role of work in healthcare services for carriage should also be explored in the working population aged <30 years. Furthermore, the *S. aureus* epidemiology in HCWs having contact with the elderly requires increased focus given the fact that nursing-home residents are a population at risk for carrying *S. aureus* and MRSA [35]. Recent antibiotic use not registered at the

screening (i.e. ceased >24 h before visit) and lack of enrichment during culturing may have caused false negatives independently of HCW status. Thus, non-differential misclassification of *S. aureus* nasal carrier status may have biased our odds ratio estimates towards null.

The major strengths of our study are the population-based design, high participation rate, large set of observations, validated outcome variable including *spa* type, gender-stratified analysis, and the adjustment for major confounders (i.e. age, BMI, smoking, etc.). Furthermore, representative data were achieved as demonstrated by the age distribution within the different age groups included.

The absence of MRSA in this study is in line with the low prevalence of MRSA in clinical *S. aureus* samples registered in the Norwegian surveillance programme during 2007–2008 [36]. Importantly, the surveillance data do not reflect a healthy population, and therefore cannot be directly compared to MRSA/MSSA colonization rates in our study, including healthy persons only (i.e. not hospitalized or institutionalized).

In conclusion, our study indicates that work in healthcare services in combination with residing with children is a high-risk cluster for *S. aureus* carriage in women. The synergism of work and home environmental risk factors should be addressed in future studies to increase our understanding of *S. aureus* epidemiology in HCWs and suggest novel targets for improved infection control strategies against exogenous MSSA and MRSA infections in patients.

ACKNOWLEDGEMENTS

We thank Bjørg C. Haldorsen, Trine Tessem, Bettina Aasnæs and Tonje Holan for excellent technical assistance. This work was supported by grants from the Research Council of Norway (grant no. 191264); Northern Norway Regional Health Authority (project no. 7150.00003, grant SFP877-09 and SFP920-10); and the Odd Berg Group Medical Research fund 2007.

DECLARATION OF INTEREST

None.
