Paper II
L-Ornithine Phenylacetate Attenuates Increased Arterial and Extracellular Brain Ammonia and Prevents Intracranial Hypertension in Pigs with Acute Liver Failure

Lars Marius Ytrebø,1 Rune Gangsøy Kristiansen,1 Hanne Mæhre,2 Ole Martin Fuskevåg,3 Trine Kalstad,4 Arthur Revhaug,4 Marı́a Jover Cobos,5 Rajiv Jalan,6 and Christopher F. Rose7

Hyperammonemia is a feature of acute liver failure (ALF), which is associated with increased intracranial pressure (ICP) and brain herniation. We hypothesized that a combination of L-ornithine and phenylacetate (OP) would synergistically reduce toxic levels of ammonia by (1) L-ornithine increasing glutamine production (ammonia removal) through muscle glutamine synthetase and (2) phenylacetate conjugating with the ornithine-derived glutamine to form phenylacetylglutamine, which is excreted into the urine. The aims of this study were to determine the effect of OP on arterial and extracellular brain ammonia concentrations as well as ICP in pigs with ALF (induced by liver devascularization). ALF pigs were treated with OP (L-ornithine 0.07 g/kg/hour intravenously; phenylbutyrate, prodrug for phenylacetate; 0.05 g/kg/hour intraduodenally) for 8 hours following ALF induction. ICP was monitored throughout, and arterial and extracellular brain ammonia were measured along with phenylacetylglutamine in the urine. Compared with ALF saline pigs, treatment with OP significantly attenuated concentrations of arterial ammonia (589.6 ± 56.7 versus 365.2 ± 60.4 μmol/L [mean ± SEM], \( P = 0.002 \)) and extracellular brain ammonia (\( P = 0.01 \)). The ALF-induced increase in ICP was prevented in ALF OP-treated pigs (18.3 ± 1.3 mmHg in ALF + saline versus 10.3 ± 1.1 mmHg in ALF + OP-treated pigs; \( P = 0.001 \)). The value of ICP significantly correlated with the concentration of extracellular brain ammonia (\( r^2 = 0.36, P < 0.001 \)). Urine phenylacetylglutamine levels increased to 4.9 ± 0.6 μmol/L in ALF + OP-treated pigs versus 0.5 ± 0.04 μmol/L in ALF + saline-treated pigs (\( P < 0.001 \)).

Conclusion: L-Ornithine and phenylacetate act synergistically to successfully attenuate increases in arterial ammonia, which is accompanied by a significant decrease in extracellular brain ammonia and prevention of intracranial hypertension in pigs with ALF. (HEPATOLOGY 2009;50:165-174.)

In patients with acute liver failure (ALF) increased intracranial pressure (ICP) leads to brain herniation, which accounts for 30% of deaths.1 Liver failure results in hyperammonemia, which leads to toxic levels of ammonia in the brain. In patients with ALF, an arterial ammonia level of >150 μmol/L has been shown to correlate with severity of intracranial hypertension2 and deaths from brain herniation.3 More recently, ammonia levels were shown to be predictive of increased ICP4 and changes in blood ammonia concentration determined death due to cerebral edema in patients with ALF.5

Abbreviations: ALF, acute liver failure; GS, glutamine synthetase; HE, hepatic encephalopathy; ICP, intracranial pressure; OP, L-ornithine phenylacetate.

Hence, ammonia-lowering strategies remain the primary therapeutic target for the treatment of increased ICP in ALF.

Studies focusing on ammonia metabolism in animal models and patients with liver failure indicate that the circulating levels of ammonia are regulated by a critical interplay of multiple organs, namely, the liver, muscles, kidney, and the small bowel, particularly in the context of liver disease. It has been shown that gut ammonia is primarily produced by the breakdown of glutamine in the small bowel through the action of the enzyme glutaminase. Many ammonia-lowering strategies have been directed toward reducing the production of ammonia in the gut, such as with nonabsorbable antibiotics and cathartics (nonabsorbable disaccharides). A recent meta-analysis concluded that there was a lack of evidence for the routine use of these strategies for the treatment of hepatic encephalopathy (HE) in patients with cirrhosis. No clinical trials have been performed with these strategies in patients with ALF. The preliminary results of a retrospective study from the U.S. liver failure group showed no effect of lactulose in ALF. Increasing ammonia detoxification as opposed to decreasing ammonia production has gained interest as an ammonia-lowering strategy. One approach is to increase the amount of substrates to stimulate ammonia-removing pathways such as glutamine synthetase (GS). GS, which is located in the brain, liver, and muscle, removes ammonia by aminating glutamate to form glutamine. The administration of the amino acids L-ornithine and L-aspartate to rats with ALF (hepatic devascularization) resulted in lowering of arterial ammonia and an increase in muscle GS activity. Here, L-ornithine and L-aspartate transaminated to glutamate in the muscle and stimulated glutamine production through GS, lowering plasma ammonia. However, instead of being excreted through the kidneys, glutamine is capable of being metabolized in the gut or kidney and regenerating ammonia, causing an ammonia-rebound effect. Hence, the treatment of hyperammonemia and intracranial hypertension in ALF remains an unmet clinical need.

Phenylacetate is safe and effectively reduces ammonia concentration and improves survival of patients with urea cycle enzyme deficiencies. Phenylacetate lowers ammonia by reducing the substrate for ammoniagenesis (glutamine) through the formation of phenylacetylglutamine, which is excreted through the kidneys. The enhanced understanding of interorgan ammonia metabolism is the basis of the hypothesis in which the combination of L-ornithine and phenylacetate would act synergistically to increase excretion of ammonia in ALF (Fig. 1). Accordingly, the administration of L-ornithine would increase glutamine production through GS in muscle, thereby capturing one molecule of ammonia. Phenylacetate would conjugate this ornithine-derived glutamine, forming phenylacetylglutamine, which is excreted into the urine, thereby eliminating ammonia from the circulation. The aims of this study were to determine whether administration of L-ornithine phenylacetate (OP) reduces arterial ammonia and brain microdialysis ammonia and whether this reduction in ammonia is associated with an

---

**Fig. 1.** Hypothesis: The coadministration of L-ornithine and phenylacetate to pigs with ALF stimulates ammonia removal by increasing glutamate in the muscle (transamination of ornithine to glutamate) and increasing glutamine production through GS. Newly formed glutamine is thus conjugated with phenylacetate and excreted as phenylacetylglutamine through the kidneys, preventing a glutamine-induced ammonia rebound effect.
attenuation in ICP in our established porcine model of ALF (induced by hepatic devascularization), which develops typical clinical and biochemical features of ALF.20-23

**Materials and Methods**

**Study Outline.** The study was performed in the Surgical Research Laboratory at the University of Tromsø, Norway, and was approved by the Norwegian Experimental Animal Board. A well-validated and well-characterized large animal model was used.20 The present study followed a pilot phase in which ALF pigs (n = 3 each) were treated with placebo, L-ornithine (0.07 g/kg/hour intravenously), or phenylbutyrate (prodrug of phenylacetate; 0.05 g/kg/hour intraduodenally). Ammonia levels in the groups treated with either L-ornithine or phenylbutyrate alone were not different from the placebo-treated ALF group (see Supporting Fig. 1). Hence, the subsequent study was performed to evaluate the effect of OP. Twenty-four female pigs weighing 27-35 kg were randomized into three groups: sham-operated + vehicle (n = 8); ALF + vehicle (n = 8); ALF + L-Ornithine + Phenylbutyrate (n = 8).

**Animal Preparation.** The pigs were kept in the animal department for at least 2 days before the experiments. Details regarding the animal room facilities, anesthesia, surgical preparation, and routine management have been reported20,23 (see Supporting Material).

T = −30 minutes was defined as the time when all catheters were in place, but before ALF induction (portacaval shunt + hepatic artery ligation). T = 0 hour was defined as the time of ALF induction or completion of abdominal surgery (sham-operated controls). At the end of the experiment (T = 8 hours) the animals were sacrificed with lethal doses of potassium and pentobarbital.

**Administration of the Study Medication.** L-Ornithine was administered intravenously (Bufa Pharmaceuticals, Utgeest, The Netherlands) at a dose of 0.07 g/kg/hour and phenylbutyrate (pro-drug of phenylacetate, Orphan Europe, Sweden) was administered intraduodenally at a dose of 0.05 g/kg/hour and compared to pigs with ALF and shams. Medication was administered as a continuous infusion for the duration of the experiment starting at T = 0 and ending at T = 8 hours. Physiological saline (9 mg/mL) was used as vehicle in both the ALF and sham groups. All groups received an equal amount of fluids.

**Hemodynamic Monitoring.** Cerebral: ICP monitoring has been described.23 Briefly, a burr hole was created over the right frontal region of the skull (1 cm lateral, 1 cm rostral from lambda), dura mater was incised, and a stable drift-free ICP transducer for continuous measurements (Codman MicroSensor; Johnson & Johnson, Langhorne, PA) was inserted into the brain parenchyma (0.5 cm ventral). For microdialysis, another burr hole was created over the right frontal region (1 cm lateral, 2 cm rostral from lambda) of the skull and a microdialysis probe (CMA 70: 10 mm long semipermeable membrane (100,000 Da cutoff) was placed into the cortex (0.25 cm ventral) as described.21 The microdialysis catheter was connected to a microinjection pump (CMA/106 Microinjection pump; CMA Microdialysis, Stockholm, Sweden) and perfused with artificial CSF (Na+ 147 mM; K+ 4 mM; Ca2+ 2.3 mM; Cl− 156 mM) at a flow rate of 3.0 μL/minute. The microdialysate was collected every 1 hour, resulting in 180 μL for biochemical analysis. Samples were stored at −20°C. At the end of the experiment a craniotomy was performed and the brain was removed, dissected, and examined for catheter placement and intracranial hemorrhage.

Cardiovascular: A 5F Edwards Swan-Ganz catheter (Baxter Healthcare, Irvine, CA) was floated into the pulmonary artery by way of the right external jugular vein. Cardiac output was measured in triplicate and the results expressed as the mean value (Vigilance, Edwards Life-sciences, Irvine, CA). The cardiac index was calculated as cardiac output/preoperative body weight. A 16G central venous catheter (Scalon T, Ohmeda, Swindon, UK) was introduced into the left external jugular vein for administration of drugs and fluids. Mean arterial pressure was measured in the left femoral artery, from which arterial blood samples were drawn. Cerebral perfusion pressure was calculated as mean arterial pressure-ICP. The urinary bladder was drained by way of a cystotomy.

**Blood and Cerebral Microdialysate Ammonia.** Ammonia was measured as previously described.24 To quantify the concentration of ammonia measured in the microdialysate, using the same microdialysis probes and microperfusion pump (at a flow rate of 3.0 μL/min), we measured the in vitro recovery rate of ammonia. This was done by immersing the probe in a solution with a known concentration of ammonia and measuring the concentration of ammonia in the collected microdialysate. The recovery rate at 3.0 μL/minute was 41.2 ± 5.4%.

**Glutamine, Ornithine, and Urea.** The determination of urea and physiological amino acids was performed as described by Dragnes et al.25 with some modifications (see Supporting Information).

**Muscle Glutamine Synthetase Activity.** To measure GS activity we applied a modified version of the methods described25,26 (see Supporting Information).

**Phenylacetylglutamine in Urine.** Pig urine samples were prepared by adding 50 μL 0.1 mM phosphate buffer solution (pH 2.4) and 50 μL 60 μM internal standard
to 50 μL urine in a 4.5 mL polypropylene tube (Sarstedt, Germany). To the same tube, 1 mL tert-butyl methyl ether was added as the extractant. The tubes were capped, mixed by shaking for 1 minute, and centrifuged at 1,700 g for 180 seconds. Then 750 μL of the supernatant was transferred to a second set of clean polypropylene tubes and evaporated to dryness under a stream of nitrogen at 40°C. The residue was then reconstituted in 100 μL mobile phase. Samples were analyzed by liquid chromatography-tandem mass spectrometry (LC/MS-MS) using Waters Acquity UPLC system with an autosampler and a binary solvent delivery system (Waters, Milford, MA) interfaced to a Waters Micromass Quattro Premier XE benchtop tandem quadrupole mass spectrometer (Waters, Manchester, UK). The system was controlled by MassLynx version 4.1. The chromatography was performed on a 2.1 × 100 mm Waters Acquity BEH C18 1.7 mm column. The mobile phase consisted of 50% methanol in 10 mM aqueous formic acid with a flow rate of 0.2 mL/minute (isocratic).

**Statistical Analysis.** Statistical analysis was performed using the Statistical Package for the Social Sciences, v. 14.0 for Windows (SPSS, Chicago, IL). Data are expressed as mean ± standard error of the mean (SEM). Two-way analysis of variance (ANOVA) was applied to test for differences within and between groups over time. An overall significance in ANOVA for repeated measurements (F-test, P ≤ 0.05) may be attributable to either the effect of group (P_G) or the interaction for group and time (P_GT). Overall significance for the effect of group means that the groups were different when all the repeated measurements were taken together (independent of time), whereas a significant interaction denotes a different time course in the two groups. When significant interactions between the groups were found, simple contrast analyses were performed to identify at which specific timepoints the groups diverged from each other. Significance of difference between groups was tested by unpaired Student’s t test to evaluate GS activity data, total amount of phenylacetylglutamine formed, and percent change in extracellular brain ammonia. Correlation coefficients were assessed using the Spearman Rank Correlation Test (data was collected from all pigs at all timepoints). P ≤ 0.05 was considered significant for all tests applied.

**Results**

One pig developed surgical complications and was excluded (ALF + OP group). Two pigs (one ALF and one sham pig) were excluded due to technical errors. Accordingly, data from 21 pigs (seven pigs in each group) were included in the present study.

**Ammonia.** Eight hours following hepatic devascularization, arterial ammonia levels significantly increased from 30.6 ± 4.7 μM (T = 0) to 589.6 ± 56.7 μM (T = 8) in the ALF group, which was significantly attenuated in the ALF + OP treated group (T = 0: 36.6 ± 4.6 μM; T = 8: 365.2 ± 60.4 μM, P_GT = 0.002). Arterial concentrations of ammonia remained unchanged in the sham group (T = 0: 34.9 ± 5.0 μM; T = 8: 50.7 ± 8.7 μM) (Fig. 2A). Arterial concentrations of urea were significantly lower in the ALF group compared to sham-operated animals (P_GT = 0.021). There was no significant difference between ALF and ALF + OP treated animals (P_G = 0.08) (Fig. 2B).

Cerebral microdialysate ammonia levels increased in the ALF animals from T = 0: 91.5 ± 39.0 μM to T = 8:
504.4 ± 158.5 μM, which was attenuated significantly in the ALF + OP treated group (T = 0: 52.8 ± 10.4 μM; T = 8: 223.5 ± 62.3 μM, P\textsubscript{GT} = 0.01). Extracellular brain ammonia concentrations remained unchanged in the sham-operated animals (T = 0: 36.9 ± 4.3 μM; T = 8: 57.7 ± 14.9 μM) (Fig. 3A). To emphasize the reduction in extracellular brain ammonia by OP, the percent increase from baseline is demonstrated in Fig. 3B. Using data from all nine timepoints, a significant positive correlation was found between arterial ammonia and extracellular brain ammonia (\(r^2 = 0.59, P < 0.001\); Fig. 3C).

**Cerebrovascular Hemodynamics.** ICP significantly increased from 6.6 ± 0.6 to 18.3 ± 1.3 mmHg in the ALF group. No significant change in ICP was observed over the study period in the ALF + OP treated animals (T = 0: 6.1 ± 0.4 mmHg; T = 8: 10.2 ± 1.1 mmHg, P\textsubscript{GT} = 0.001). No changes in ICP were observed in the sham-operated group (T = 0: 5.3 ± 0.2 mmHg; T = 8: 8.3 ± 0.9 mmHg; Fig. 4A). Collecting all data, significant positive correlations were found between ICP and arterial ammonia (\(r^2 = 0.37, P < 0.001\); Fig. 4B) and between ICP and extracellular brain ammonia (\(r^2 = 0.36, P < 0.001\); Fig. 4C).

**Cardiovascular Hemodynamics.** Cardiac index increased in both the ALF and ALF + OP-treated groups, whereas it slightly decreased in the sham-operated group (P\textsubscript{GT} = 0.01). Mean arterial pressure decreased over time in both the ALF and ALF + OP-treated groups, whereas it remained stable in the sham-operated group (P\textsubscript{GT} < 0.001). Cerebral perfusion pressure was lower in the ALF and ALF + OP-treated groups compared to sham-operated controls (P\textsubscript{GT} < 0.001), which remained unchanged throughout the experimental period (Table 1).

**Glutamine and Ornithine.** Arterial, muscle, and brain glutamine levels were significantly higher in ALF animals compared to sham-operated controls (Table 2). In the ALF + OP-treated animals, arterial glutamine levels were markedly higher (\(\approx 300 \mu M\)) as were muscle glutamine levels (\(\approx 360 \mu M\)) compared to the untreated ALF group. Brain glutamine levels were not significantly different in the ALF + OP animals compared with the untreated ALF group. Although the muscle glutamine levels were similar in the ornithine-treated group com-

---

Fig. 3. (A) Extracellular brain ammonia concentrations over time: significant interaction between ALF versus sham (P\textsubscript{GT} < 0.001) and ALF versus ALF + OP (P\textsubscript{GT} = 0.01). (B) Change in extracellular brain ammonia (expressed as percent baseline) over the duration of the study period in the three groups: significant interaction between ALF versus sham (P\textsubscript{GT} < 0.001) and ALF versus ALF + OP (P\textsubscript{GT} = 0.04). Contrast analysis: †ALF versus sham. (C) Correlation between arterial ammonia and extracellular brain ammonia (\(P < 0.001\)) (■ = SHAM, ○ = ALF, ▲ = ALF + OP).
pared with the ALF + OP-treated group, the arterial glutamine concentration was about 360 μM less in the ALF + OP-treated group. Due to the fewer number of animals in the ornithine and phenylacetate alone groups, formal statistics were not possible to perform. In the OP-treated group there was a significantly higher concentration of the ornithine-treated ALF animals in the arterial plasma, muscle, and brain compared to ALF, indicating the bioavailability of the infused ornithine to the muscle. Similar results were found in the ornithine-treated animals (see Supporting Table 1). The muscle and brain ornithine levels were not significantly different between the ALF animals compared to sham-operated controls (Table 2).

**Muscle Glutamine Synthetase Activity.** Hindleg muscle GS activity tended to be higher in the ALF (19.1 ± 9.9 nU/mg protein; 115% higher than sham) and the ALF + OP groups (40.6 ± 21.1 nU/mg protein; 356% higher than sham) compared with the sham-operated group (8.9 ± 1.3 nU/mg protein), but these differences did not reach statistical significance (ALF versus sham, \( P = 0.10 \); ALF versus ALF + OP; \( P = 0.82 \)) (Fig. 5).

**Urinary Phenylacetylglutamine.** The concentration of phenylacetylglutamine increased significantly with time in the ALF + OP treated group (T = 8; 4.9 ± 0.6 μmol/L) compared to the untreated ALF group (T = 8; 0.5 ± 0.04 μmol/L; \( P_{\mathrm{GT}} < 0.001 \)) (Fig. 6). The total amount of phenylacetylglutamine excreted (concentration × urine volume) was also significantly higher in ALF + OP-treated group (T = 8; 0.32 ± 0.11 μmol) compared to the untreated ALF group (0.02 ± 0.01 μmol; \( P = 0.04 \)). No correlation was found between concentrations of phenylacetylglutamine in the urine and concentrations of ammonia in the blood (data not shown).

**Discussion**

The prevention and treatment of intracranial hypertension in patients with ALF remains an unmet clinical need. The hypothesis that ammonia is central in the pathogenesis of HE from over 100 years ago has been confirmed with several studies in the past 10 years pointing to the important relationship between arterial ammonia levels and the severity of cerebral edema, intracranial hypertension, and deaths related to brain herniation.2-5,27 The most important observation of this study was the demonstration that the combination of L-ornithine and phenylbutyrate (prodrug of phenylacetate), compounds that are already being used individually in humans, act synergistically to significantly attenuate the increase in arterial and cerebral microdialysis ammonia that is asso-
associated with a prevention of increased ICP in a liver devascularized model of ALF in the pig.

Many ammonia-lowering strategies have focused on lowering the production of ammonia in the large bowel using nonabsorbable disaccharides and antibiotics. Lactulose is commonly used in clinical practice but there is insufficient evidence to support whether it is beneficial in patients with HE, as its efficacy has yet to be proven in a high-quality randomized trial. Similarly, administration of nonabsorbable antibiotics has not been proven to be an effective method of reducing ammonia or treating HE in patients with ALF. Another strategy to reduce the production of ammonia in the gut is by maintaining patients on a low-protein diet. This strategy was recently tested in a population of patients with cirrhosis but a low-protein diet was paradoxically shown to be deleterious, resulting in a catabolic state, increased protein breakdown, and no improvement in the severity of HE.28

Another ammonia-lowering strategy is to increase the capacity of ammonia detoxification. L-ornithine + L-aspartate given to patients with cirrhosis has been shown to be beneficial in lowering plasma ammonia and in improving the mental state of patients with early HE.29 Similar conclusions were found in L-ornithine + L-aspartate-treated portacaval shunted rats.30 L-ornithine + L-aspartate is thought to reduce the ammonia concentration by conversion of ammonia to glutamine by the enzyme GS in the muscle. However, more recently, observational studies in patients with liver failure demonstrated that the glutamine generated following administration of L-ornithine + L-aspartate was associated with a rebound hyperammonemia that could be prevented by administration of phenylacetaete.15 This observation inspired investigators from the UK to propose a new hypothesis that involves coadministration of L-ornithine and phenylacetaete that would increase ammonia removal through glutamine production (using L-ornithine) and preventing a glutamine-induced ammonia rebound (using phenylacetaete).15

Our study was designed to test this hypothesis. Accordingly, during the pilot phase of our study the administration of either L-ornithine or phenylacetaete individually did not have any significant effect on ammonia reduction but the combination worked synergistically to significantly attenuate an increase in ammonia (Supporting Fig. 1). In the OP-treated ALF animals, concentrations of ammonia in the arterial blood were reduced by 38% (at T = 8) compared to the untreated ALF animals. In order to monitor changes in concentrations of brain ammonia over time, a microdialysis catheter was placed in the frontal cortex. An increase in extracellular brain ammonia was observed over the experimental period in pigs with ALF, which was significantly prevented in ALF + OP-treated animals. A significant correlation between arterial ammox-

nia and extracellular brain ammonia was demonstrated, supporting the fact that systemic hyperammonemia is associated with increased concentrations of ammonia in the brain. Brain tissue ammonia concentrations were not measured due to the unreliability of such measurements introduced by the relatively long time interval between the death of the animal, removal of the skull, and dissection of the brain, which could be as long as 15 minutes owing to the thickness of the pig skull. The reduction in arterial and microdialysis ammonia in the OP-treated ALF animals was associated with prevention of an increase in ICP that was not significantly different from sham-operated animals. In contrast, ICP increased by 121% in the untreated ALF animals compared to sham animals over an 8-hour period following hepatic devascularization. In this model, animals with ALF develop a hyperdynamic circulation with increased cardiac index and decreased mean arterial pressure.20,31 Cerebral perfusion pressure decreased in ALF pigs as a consequence of increased ICP and decreased mean arterial pressure. Eight hours of OP treatment did not significantly affect the hemodynamics in pigs with ALF (Table 1), and therefore the prevention of increased ICP due to OP treatment in ALF animals is unlikely due to improved cerebral perfusion. In this model our previous studies have shown that the observed increase in ICP is independent of changes in cerebral blood flow.21

In our study we demonstrated a significant correlation between ICP and arterial concentrations of ammonia, as well as between ICP and extracellular concentrations of brain ammonia. Additionally, we observed a significant correlation between ICP and extracellular concentrations of brain ammonia. The importance of extracellular brain ammonia in the pathogenesis of intracranial hypertension highlighted in this study confirms our recent observation where a prevention in increased ICP using extracorporeal albumin dialysis was associated with a decrease in extracellular cerebral ammonia and not arterial ammonia.21,24 Although previous studies have clearly shown that hyperammonemia is associated with brain edema in humans and model systems, data aimed at treatment of hyperammonemia showing direct effects on the brain have been lacking. Our data provide novel evidence that reduction in systemic ammonia does indeed result in prevention of increased ICP, firmly emphasizing ammonia as an important central therapeutic target in ALF and HE.

Because there is no increased urea production in pigs with liver devascularization/ischemia (Fig. 2B), this is an excellent model of ALF to test ammonia-lowering strategies that are independent of the urea cycle. There was a strong trend toward an increase in the muscle GS activity in both the ALF groups both demonstrating an increase in GS activity compared to sham animals but with an even further increase observed in the ALF + OP-treated animals. However, these results did not reach statistical significance. Importantly, the data suggest that OP can stimulate glutamine production through GS solely by increasing its substrate.

In both the ornithine alone and OP-treated groups, an increase in concentration of ornithine and glutamine was observed in the arterial plasma and muscle compared to ALF. The increase in glutamine was associated with a substantial and significant lowering of arterial ammonia in only the OP-treated animals. The difference in ammonia between the ornithine alone and the OP-treated
groups was of the magnitude of \( \approx 360 \mu M \). Feedback GS inhibition due to glutamine may play an important role in understanding the synergistic effect of OP. This feedback inhibition may be relieved upon the removal of glutamine by glutaminase; however, this in turn produces ammonia and contributes to hyperammonemia. Removing glutamine by phenylacetate relieves GS inhibition, allowing for further glutamine production and ammonia removal and contributes to lowering blood ammonia.\(^{32-34}\) Our data suggest that OP treatment lowers ammonia systematically in ALF animals and subsequently attenuates the concentration of ammonia in the brain. However, whether OP has a direct effect in lowering ammonia in the brain needs to be further evaluated. Brain ornithine levels were also significantly elevated in both the ornithine alone and the OP-treated animals but this increase was only modest compared with the concentration of ornithine in the arterial plasma and muscle from the same animals. This therefore may indicate the ornithine concentrations detected in the brain may be a result from contamination from the elevated concentration of ornithine in the blood. In the brain, OP treatment resulted in a reduction in glutamine that did not reach statistical significance compared with the ALF group.

In support of the hypothesis based around combining L-ornithine and phenylacetate, we were able to show clearly an increase in the excretion of phenylacetylglutamine in the urine in ALF + OP-treated pigs compared to saline-treated ALF pigs. Concentrations of phenylacetylglutamine in the urine increased over time in ALF + OP. However, there was a lack of stoichiometry between the reduction in arterial ammonia concentration and the increase in urinary phenylacetylglutamine. This is likely to be due to differences in conjugation pathways between humans and pigs. In humans, phenylacetylglutamine is the main renal excretion product of the reaction between phenylacetate and glutamine, but in pigs this association is less clear, as there are a number of additional by-products of phenylacetate metabolism.\(^{35}\) It is also possible that the 360 \( \mu M \) difference in the arterial glutamine between ornithine alone and OP-treated ALF animals may be explained by the delay in excretion of the conjugate as observed in a study with OP in cirrhotic rats.\(^{36}\)

In this study the protocol involved the administration of L-ornithine and phenylacetate as a continuous infusion for the duration of the experiment (8 hours). The administration and dosage/ratio of L-ornithine and phenylacetate was based on pilot studies in this model and in rats with cirrhosis (data not shown). However, further work is needed in order to define the optimal dosage/ratio for this novel treatment concept and whether bolus infusion followed by continuous infusion would be a better alternative. As seen in Fig. 2, OP attenuated hyperammonemia 4 hours following the start of infusion. A bolus infusion would possibly shorten this period, erasing the delay due to the absorption time of phenylacetate from the gut. Furthermore, at the time when the present experiments were performed, phenylacetate was only available as an oral formulation (intragastric/intraduodenal use).

In conclusion, the administration of OP to pigs with ALF successfully reduces arterial and extracellular brain ammonia levels and as a result prevents any rise in ICP during the experimental period. Because both L-ornithine and phenylacetate are already used in humans, this novel treatment concept might quickly be translated into a much-needed therapy for the prevention and the treatment of increased ICP in patients with ALF.

Acknowledgment: The authors thank Janne Andreasen, Monica Figenschou, Hege Hagerup, Harry Jensen, and Mehrdad Sobkhaz for excellent technical support during the experiments as well as Tom Wilsgaard for excellent statistical advice. We thank Dr. S. Hodges and Dr. G. Wright who helped with the development of the experimental ideas leading up to this study. We thank the staff at the Department of Clinical Chemistry, University Hospital of North Norway, for help and support during the early phase of these experiments.

Paper II
Supporting Information

1. **Legend to Supporting Figure 1.**

Arterial ammonia concentration in pigs with ALF (n=3), ALF + O (n=3), and ALF + P (n=3). Mean±SEM. There is no significant difference between all 3 groups.

2. **Animal preparation**

   Briefly, the animals were fasted overnight, but with free access to water. They were premedicated with an intramuscular injection of 20 mg/kg ketamine (Ketalar, Pfizer, Oslo, Norway) and 1 mg atropine (Atropin, Nycomed Pharma, Oslo, Norway). Anesthesia was induced with an intravenous bolus of 10 mg/kg pentobarbital (Pentobarbital, Nycomed Pharma, Oslo, Norway) and 10 μg/kg fentanyl (Leptanal, Janssen Pharmaceutica, Beerse, Belgium) and maintained during surgery with a central venous infusion of 4 mg/kg/hr pentobarbital, 0.02 mg/kg/hr fentanyl, and 0.3 mg/kg/hr midazolam (Dormicum; Roche, Basel, Switzerland). The pigs underwent a tracheotomy, were intubated and ventilated (FiO₂=0.5) on a volume-controlled respirator (Servo 900, Elema-Schönander, Stockholm, Sweden). Tidal volume was adjusted by means of repeated arterial blood gas analyses to maintain PaCO₂ between 4.5 and 5.0 kPa during surgery. Ventilation was not altered after T=0 hrs. Core body temperature was maintained normothermic at 38.5±1°C with a heating pad and blankets. ALF was induced with an end-to-side portacaval shunt followed by ligation of the hepatic arteries and all animals were administered intravenous saline, glucose and albumin as described previously²⁰,²³.

3. **Measurement of glutamine, ornithine and urea**

   In the arterial samples the compounds were extracted by homogenizing 360 μl blood plasma with 36 μL of 2 mmol/L norleucine and 40 μL 35% sulphosalicylic acid. Muscle (hind leg)
and brain (frontal cortex) tissue samples were extracted by homogenizing 200mg of tissue with 200µl of 20mmol/L norleucine and 800µl distilled water and 200µl 35% sulphosalicylic acid. Norleucine served as an internal standard. The suspension was centrifuged and an aliquot of the supernatant was submitted to analysis. The concentration of urea and physiological amino acids was determined using a Biochrom B30 amino acid analyzer (Biochrom, Cambridge, UK) equipped with a lithium citrate equilibrated column. The signal was analyzed by Chromeleon software (Dionex, Sunnyvale, CA, USA) and compared with A9906 physiological amino acids (Sigma Chemical Co., St. Louis, MO, USA).

4. Muscle glutamine synthetase activity

Tissue was homogenized with 10 x volume of the imidazole-EDTA buffer, and subsequently diluted using the same buffer. Reaction buffer was composed of the following: Imidazole (80.7mM), Sodium arsenate (40.3mM), Sodium ADP (81uM), L-Glutamine (30.3mM), MnCl₂·4H₂O (1mM). The pH was adjusted to 7.0. Immediately before use aliquots were diluted 1:1 with 1M NaOH and then adjusted to pH 7.0. This solution was further diluted 1:1 with water. Tissue homogenate (80µl) was mixed with 70µl reaction mixture. Hydroxylamine solution (2M; 10µl) was added immediately before the samples were incubated (20min) at 37 °C under gentle shaking. The reaction was terminated by adding 80µl of a solution of 2.42% FeCl and 1.45% TCA in 1.82% HCl, insoluble material was removed by centrifugation and the absorbance of the supernatant was measured at 540nm. Blanks were made as the incubation mixtures, except that instead of the enzyme preparation (i.e. tissue homogenate) 80µl of the imidazole-EDTA (homogenization buffer) buffer was added. Glutamic acid-γ-hydroxamate was used as standard (range 0-10mM). Appropriate dilutions were prepared as needed by adding water.
Calculations;

\[
\text{Glutamine + } H_2\text{NOH} \stackrel{\text{ADP; Mn}^{2+}; \text{AsO}_4^{3+}}{\text{GS}} \rightarrow \text{Glutamyl-}\gamma\text{-hydroxamate + NH}_3
\]

As shown in the formula, the relation is 1:1, which allowed us to calculate the enzyme activity directly from the concentrations in the standard curve.

5. Extraction procedure and liquid chromatography tandem mass spectrometry for measurement of phenylacetylglutamine in urine

The mass spectrometer was operated in both positive and negative electrospray ion mode and spray voltage was 3kV. Sample injection volume was 3µl and the injection interval was 3min. Autosampler temperature, 7°C; desolation gas temperature, 260°C; source temperature 120°C; desolation gas flow 800L/h; cone gas flow, 40L/h; collision gas pressure 2.8 x 10^{-3}mBar (argon); ion energies, 1V for both quadrupoles. For quantitative analysis of phenylacetylglutamine, the following MRM transitions were used: \(m/z\) 263→145, \(m/z\) 263→127 (qualifier ion) and 265→130 (qualifier ions). MRM transition 165→59 and 165→121 were used for the internal standard. The dwell time was set to 50ms for each transition. The method showed good linearity and reproducibility with a correlation coefficient \((r)\) of >0.99 and a coefficient of variation of < 9%.

Chemicals

Analytical grade tert-butyl methyl ether, formic acid and HPLC grade methanol were supplied by Merck (Darmstadt, Germany). Sodium dihydrogenphosphate dihydrate was purchased from Fluka (Sigma-Aldrich, St. Louis, MO). Phenylacetylglutamine was supplied by Bachem (Bubendorf, Switzerland). 3-(4-hydroxyphenyl)propionic acid was purchased from Aldrich (Sigma-Aldrich,
Steinheim, Germany). Stock solution for liquid chromatography was prepared by dissolving phenylacetylglutamine in methanol to obtain a concentration of 939 µM. Urine standard samples were prepared by dilution of the stock solution with phenylacetylglutamine free urine from pigs at the following concentrations: 0.3, 1, 10, 30, 70 and 100µM. Quality control (QC) plasma samples at 90 and 5µM were prepared in the same manner. The samples and standard solutions were stored at -70°C before analysis.
Supporting Table 1

Glutamine and ornithine levels in arterial blood, muscle, and brain at t=8hrs in pigs with ALF treated with O (n=3) and P (n=3).
