Abstract:	<p>Living (Rose Bengal stained) benthic foraminifera were studied in the topmost sediments of 5 multi- and box cores collected on the continental shelf, upper and lower slopes and of the Chukchi Sea in order to provide background information on modern benthic foraminiferal distribution, useful for future studies. Sediment cores were collected during August-September 2015, when the area is seasonally ice-free. Benthic foraminiferal contents in the 63-125 µm and >125 µm size fractions are discussed in terms of water masses distribution, sedimentological (grain size) and organic geochemical (total organic carbon, total nitrogen, C/N ratio and δ13Corg) characteristics of the surface sediments. Marine organic carbon-rich clay sediments characterize the faunal microhabitats. Despite relatively high organic carbon contents, standing stocks of living benthic foraminifera are generally low, especially for the 63–125 µm size fraction. This low living stock seems to reflect post-bloom conditions in August and September in the area. The reduced supply of fresh organic carbon also affects faunal microhabitats in the sediment with a concentration of living fauna in the upper 2 cm of the sediment. Over the Chukchi Sea shelf, a relatively mixed upper sediment layer likely due to bioturbation or bio-structures induce a disturbed vertical distribution in the sediment. Corrosive Pacific-derived bottom water over the shelf likely explains the relative importance of agglutinated vs. calcareous fauna in this shallow setting. Our results suggest that, in a post-bloom context, the main environmental control on benthic foraminiferal assemblages in the Chukchi Sea is the nature of the bottom water masses.</p>

34 This study was conducted under the bilateral visiting program between Korea and France
35 funded by Korean Research Foundation (to SIN, 2014K1A3A1A21001427) and the Campus France
36 PHC Star. We thank the captain and crews of the RV Araon. We are very grateful to Sabine Schmidt
37 who performed the ^{210}Pb analysis and Marie-Claire Perello for the grain size analysis at EPOC. We
38 also thank Kwangkyu Park at KOPRI for the organic geochemical analyses. We wish to thank Jimmy
39 Daynac for the SEM pictures and the photographic plate. P.-A. Dessandier was supported by The
40 Research Council of Norway through its Center of Excellence funding scheme for CAGE, project
41 number 223259. This paper benefited from the very constructive comments of two anonymous
42 reviewers.

1. Introduction

The Arctic Ocean is the smallest and shallowest of the world's five major oceans but it plays an essential role in the global oceanic circulation and the regulation of the Earth's climate system. Since the last decades the Arctic region has undergone significant and rapid climate changes with a reduction of sea-ice cover and thickness, an increase in length of sea-ice melt season (e.g. [20, 44, 55]), as well as a rise in sea surface temperatures (SST) and temperatures of water masses flowing into the Arctic Ocean (e.g. [85, 86, 107, 109]).

Recent benthic foraminifera in the Arctic Ocean have been investigated by several authors during the last five decades [9, 37, 41, 42, 50, 64, 77, 78, 79, 94, 102, 103, 104]. The rare studies which distinguished stained (living) benthic foraminifera from fossil (dead) faunas in Arctic sediments usually demonstrate a close correlation between the distribution of foraminiferal species and bottom water masses [9, 37, 42, 64]. In the global Ocean, living benthic foraminiferal studies highlight the impact of a wide range of processes upon foraminiferal distributions among which are food supply, salinity, temperature, oxygen, tides and currents, substrate, light penetration, the presence of seagrass and macroalgae, as well as competition and predation ([61] and references therein). Of these multiple factors and in addition to bottom water mass characteristics, food availability and competition for food are thought to control to a high extent foraminiferal associations in the Arctic Ocean (e.g. [102, 103, 104]).

In this paper, we present results from living foraminiferal population collected in the northern sector of the Chukchi Sea, one of the major gateways of the Arctic Ocean. Summer sea-ice in the western Arctic, especially in the Chukchi Sea, has been rapidly declining during the last decades (e.g., [19, 20]). Recently, Yun et al. [111] have also shown that the primary production in the Chukchi Sea presents some decreasing trend for the last decades, probably associated with fresh water input related to sea-ice melting. However, there are very few studies focusing on the distribution of benthic foraminifera in this area. Osterman et al. [64] reported the distribution of benthic foraminifera in the Chukchi Sea but their study was only based on the >125 μm size fraction

70 and did not distinguish living from dead faunas. Here, we present the first data on the distribution of
71 living benthic foraminifera $>63 \mu\text{m}$ in the northern Chukchi Sea, from the continental shelf to the
72 lower slope and discuss their distributional pattern in view of the local environmental setting. We
73 believe that the present study is absolutely central for a better knowledge of Arctic foraminiferal
74 ecology and in future efforts aiming at reconstructing past environments in the area of the Chukchi
75 Sea.

76 2. Regional setting

77 The Chukchi Sea, one of the largest marginal sea of the Arctic Ocean, extends from the Bering
78 Strait in the south to the edge of the Canadian basin in the north (Fig. 1). Most of the Chukchi Sea
79 constitutes a large shallow shelf which deepens progressively towards the north (Fig. 1). To the north
80 of the shelf system, the Chukchi Borderland includes two subsea formations that extend into the
81 Amerasian Basin: the Chukchi Plateau and the Northwind Ridge [68].

82 The Chukchi Sea is strongly influenced by fresh Pacific waters entering through the Bering
83 Strait. The annual volume transport averages about 0.8 Sv northwards [71, 105]. This inflow of fresh
84 Pacific waters is stronger in summer and relatively weak in winter. Two water masses of Pacific origin
85 dominate the Chukchi Sea circulation [17]: the Bering Sea Water (BSW) and the Alaskan Coastal
86 Water (ACW). The ACW is carried by the Alaskan Coastal Current (ACC) into the Chukchi Sea, flowing
87 northwards along the Alaskan coast with a transport volume of 0.1 Sv. It is a relatively warm, low
88 salinity and nutrient-poor water mass [40, 106]. The remaining 0.7 Sv of Pacific waters flowing into
89 the Chukchi Sea is made of BSW, a mixture of Anadyr Water and Bering Shelf Water [17]. These
90 waters are saltier and richer in nutrients than the ACW [87]. In the western sector of the Chukchi Sea,
91 the seasonal Siberian Coastal Current (SCC; 0.1 Sv) flows southwards along the coast and deflects
92 fresh and cold waters into the central Chukchi Sea [101, 105]. Seasonal variations in Pacific water
93 inflow and sea-ice cover lead to a seasonal cycle of water mass stratification [40, 105]. In summer,
94 the inflow of Pacific water, especially via the ACC, transports heat into the Chukchi Sea leading to a
95 stronger stratification of the surface layers [108]. Conversely, water column is well-mixed from fall to

1 96 spring, the inflow of Pacific water becoming cooler and denser due to brine releases during sea-ice
2 97 formation [100]. To the north of the Chukchi Shelf, surface circulation is driven by the two main
3
4 98 surface current systems of the Arctic Ocean: the Beaufort Gyre (BG) and the Transpolar Drift (TPD).
5
6
7 99 Warm and salty Atlantic Intermediate Water (AIW) flows along the Chukchi slope, following the shelf
8
9 100 break from west to east, between approximately 200 and 900 meters below sea level, and
10
11 101 submerges cold Arctic Deep Water (ADW) which circulates within the deep Arctic basins (Fig.1; [1, 13,
12
13
14 102 91]).

15
16 103 The Chukchi Sea is characterized by a first-year ice, making this area particularly sensitive to
17
18 104 the present overall reduction in Arctic sea-ice concentration [18, 24]. Over the satellite record, the
19
20
21 105 Chukchi Sea has displayed the sharpest downward trends in Arctic sea-ice extent, the September sea-
22
23 106 ice edge being now located far north of the continental shelf break [20]. Shimada et al. [85] and more
24
25
26 107 recently Serreze et al. [83] suggested that the recent reduction in sea-ice concentration was
27
28 108 essentially triggered by the warming of the inflowing Pacific water. Atmospheric temperature and
29
30
31 109 circulation may also influence the seasonal melting of ice [83].

32
33 110 The Chukchi Sea is generally considered as a highly productive region on the edge of the
34
35 111 largely oligotrophic Arctic basin [57] as the result of the inflow of fresh and nutrient-rich Pacific water
36
37
38 112 into the Chukchi continental shelf. However, a recent study by Yun et al. [111] has shown a
39
40 113 decreasing trend in primary production in the Chukchi Sea during the last decades with relatively
41
42 114 large regional variation. Spatial and temporal variations in the productivity of the Chukchi Sea are
43
44
45 115 related to changes in duration, thickness and extent of seasonal sea-ice which control light
46
47 116 availability and surface water stratification from sea-ice melting [36, 39, 98, 111]. Mean average
48
49
50 117 primary productivity in the Chukchi Sea is generally higher over the shallow shelf which experiences
51
52 118 seasonal sea-ice compared to the northern sector of the Chukchi Sea [111]. Primary production rates
53
54 119 over the southern shallow sector of the Chukchi Sea average $80-90 \text{ g C m}^{-2} \text{ y}^{-1}$ and progressively
55
56
57 120 decrease toward the slope ($<50 \text{ g C m}^{-2} \text{ y}^{-1}$) and over the deep Arctic basin ($<20 \text{ g C m}^{-2} \text{ y}^{-1}$) [36, 39,
58
59 121 74, 98]. Intense blooms are observed with ice edge retreat [97], in the open water of marginal ice

122 zone (MIZ; [65]), starting with an ice algae bloom in May followed by a strong but brief
123 phytoplankton bloom in June [99]. A recent study also revealed intense phytoplankton blooms
124 beneath sea-ice in the Chukchi Sea [2]. However, several studies show the negative effect of fresh
125 water input resulting from sea-ice melting on the nutrient concentration and therefore primary
126 production in this area [22, 110, 111].

3. Materials and methods

3.1. Sample collection

This study is based on 9.8 cm diameter multicores and push cores subsampled from boxcores collected at five stations in the Chukchi Sea during the ARA06C cruise onboard the RV ARAON, between August 25th and September 9th, 2015 (Fig. 1, table 1). Upon recovery, sediment cores were sliced onboard every 0.5 cm from the surface down to 2 cm, then every centimetre down to 5 cm. For each station, one sediment core was used for benthic foraminiferal analysis and another one for sedimentological and geochemical analyses. Temperature and salinity profiles through the whole water column, as well as chlorophyll *a* (Chl *a*) profiles for the upper water column were measured at Sts. 01A, 02, 03 and 04 using a conductivity temperature depth (CTD) profiler and a fluorometer sensor respectively. Sea-ice conditions (drift ice) hindered the deployment of the profiler at St. 05.

3.2. Sedimentological and geochemical analyses

Grain size analysis were conducted at Environnements et Paléoenvironnements Océaniques et Continentaux (EPOC, France) using a laser diffraction particle size analyser (Malvern Mastersizer 2000 hydro G). Measurements along the top 5 cm of each core were performed on freeze-dried sediment. Grain size-spectra derived from downcore measurements display a unimodal distribution at all stations. We therefore consider the median diameter of the particle size distribution D_{50} as a reliable measurement of the mean grain size in the sediment cores investigated in the present study.

Sedimentary total organic carbon (TOC) and total nitrogen (TN) contents as well as stable isotope composition of organic carbon ($\delta^{13}C_{org}$) were measured at the Korea Polar Research Institute

147 (KOPRI, South Korea) using an EA-IRMS system (Flash 2000-Delta V, Thermo Scientific). Total carbon
148 (TC) and TN were measured on freeze-dried sediment. TOC and $\delta^{13}\text{C}_{\text{org}}$ were analysed on carbonate
149 free sediment after HCl (10%) treatment. Finally, TOC was calculated using the following equation
150 [88]: $\text{TOC (\%)} = [100 - (8.333 * \text{TC})] / [(100 / \text{TOC}') - 8.333]$. The analytical error was less than $\pm 0.1 \%$
151 for TN and TOC contents and $\pm 0.1 \text{‰}$ for $\delta^{13}\text{C}_{\text{org}}$. TN and TOC are expressed as the mass weight of dry
152 bulk sediment (wt. %). The C/N ratio was calculated by dividing TOC by TN.

153 ^{210}Pb and ^{226}Ra were measured at EPOC (France) by γ spectrometry analytical technique on
154 freeze-dried sediment of the first 7 cm of core 01A (St. 01A). ^{210}Pb in excess of equilibrium with ^{226}Ra ,
155 $^{210}\text{Pb}_{\text{xs}}$, was calculated as the difference between measured ^{210}Pb and ^{226}Ra .

156 3.3. Living (stained) benthic foraminiferal analysis

157 Sample treatment and faunal analysis mostly follow the FOBIMO standardized protocol [76].
158 Benthic foraminiferal samples were preserved in a 1.5 g L^{-1} solution of Rose Bengal in 96% ethanol in
159 order to stain the living endoplasm of benthic foraminifera according to Murray and Bowser [60] and
160 Walton [96]. This concentration is lower than recommended by the FOBIMO protocol (2 g L^{-1}), but
161 has been shown to efficiently stain the living organism in many studies [e.g., 25, 28]. The samples
162 were repeatedly homogenised immediately after staining. For more precision, the real volumes of
163 sediment were measured [76]. Samples were wet sieved through $63 \mu\text{m}$ and $125 \mu\text{m}$ mesh screens.
164 Benthic foraminiferal analysis was performed on both the $63\text{-}125 \mu\text{m}$ and $>125 \mu\text{m}$ size fractions. All
165 stained individuals were hand-sorted under wet condition from the surface down to 5 cm for the
166 $>125 \mu\text{m}$ fraction and from the first centimetre only for the $63\text{-}125 \mu\text{m}$ fraction. The choice of
167 limiting the analysis of the $63\text{-}125 \mu\text{m}$ fraction to the top first centimetre stems from the extremely
168 low abundance of living fauna in the 0-1 cm interval of this size fraction at each investigated station
169 (precluding the existence of $<125 \mu\text{m}$ fauna below the depth of 1 cm) as well as from the time
170 consuming effort for such low gain. The coloration of Rose Bengal stained specimens considered as
171 living at the time of sampling may vary among species from light pink to dark red or brownish violet
172 [76]. Consequently, only specimens with all chambers coloured (except the last one) were considered

173 as living. Some non-transparent tests (miliolids or agglutinated taxa) were broken, after
174 identification, to ensure that protoplasm was stained. All specimens were identified to species levels
175 if possible following the generic classification of Loeblich and Tappan [51].

176 We considered as major species the ones representing at least 5% of the foraminiferal
177 assemblages. Faunal densities were standardized for a sediment volume of 50 cm³. Living standing
178 stock represents the total number of living individuals counted per station in each size fraction,
179 normalized for a 100 cm² sediment area according to Goineau et al. [31] and Dessandier et al. [25].
180 Three biodiversity indices were calculated using the PAST software [38]: the species richness (S,
181 number of species present in a sample), the Shannon index H' [84] and the Evenness index E [12].

182 4. Results

183 4.1. Environmental, sedimentological and organic geochemical settings 184 during the sampling period

185 At the end of August 2015, sea-ice was very thin and was only found north of the sampling
186 area (Fig. 1). A continuous northward retreat of the sea-ice edge occurred until the end of September
187 2015. Therefore, all the investigated stations were free of ice at the time of sampling.

188 An upper 20 m thick low salinity (<30) surface layer characterizes all stations under the
189 influence of sea-ice melting (Fig. 2a). Changes toward lower surface salinities (ca. 29.5 to 26.5) and
190 lower surface temperatures (ca. 1.5 to -1°C) from St. 01A to St. 04 reflect the increasing proximity to
191 the sea-ice edge. This surface mixed layer overlays the colder and saltier Pacific water with typical
192 signature of -1.5°C and 33 extending down to 200-250 m over the slope and deep sectors of the
193 Chukchi Sea (Fig. 2a). This water mass bathes the sediment-water interface at the shallow (110 m) St.
194 01A (Fig. 2a). The AIW with mean salinities of 35 and temperatures up to 0.8-0.9°C is observed from
195 200-250 m to ca. 750 m (Fig. 2a), and therefore characterizes the bottom water at the slope Sts. 05
196 (350 m) and 03 (750 m). The ADW occupies the deeper >750 m water column at Sts. 02 (2100 m) and
197 04 (2300 m) with typical temperatures <0°C and stable salinity of 35 (Fig. 2a). Chl *a* profiles within the

198 upper water masses of Sts. 01A, 03, 02 and 04 are given in Figure 2b. Chl *a* concentrations measured
199 at all stations range from ca. 0.5 to 1.6 $\mu\text{g L}^{-1}$ within the top 80-100 m water depth. These values are
200 relatively low when compared to values of Chl *a* concentrations (about 1-10 $\mu\text{g L}^{-1}$) commonly
201 measured in the study area during bloom periods in June and July [2, 65, 97]. Maximum Chl *a*
202 concentrations over the shelf (St. 01A; 0.6-0.7 $\mu\text{g L}^{-1}$) occur in shallower depth, around 20 m water
203 depth, than over the upper and lower slope stations (Sts. 03, 02, 04) where peak values of 0.6 to 1.6
204 $\mu\text{g L}^{-1}$ are found deeper around 60-70 m water depth.

205 Sedimentological and geochemical analyses in the surface sediment are shown in Figure 3. At
206 all stations, sediment grain size ranges from clay to fine silt ($D_{50} = 8-12 \mu\text{m}$). The shallowest St. 01A
207 displays high TOC and TN contents (>2.5 and 0.3 wt. %, respectively) compared to other stations (≤ 1
208 and 0.15 wt. %). The $\delta^{13}\text{C}_{\text{org}}$ values range from -24 to -21 ‰ and agree with other evidences [36, 62,
209 63] for a dominant marine origin of the organic matter in sediments of the Chukchi Sea and more
210 generally in sediments of the Amerasian Arctic. This marine origin is confirmed by the C/N ratio
211 which, within the top 2 cm of most of the stations, ranges between 6 and 8, revealing typical
212 signature of marine algae [70]. These ratios also indicate that this marine organic matter was
213 subjected to limited degradation processes within the water column and the top part of the
214 sediment layers [56]. C/N ratio values close to 9 on average at St. 01A however suggest that
215 sediment at this shelf station might contain a terrigenous component, though with limited
216 contribution to the total organic matter content. $^{210}\text{Pb}_{\text{xs}}$ activity profile (Fig. 4) was measured in the
217 first 7 cm of the sediment in order to highlight possible bioturbation or bio-structures in core 01A
218 locating on the shelf. The vertical profile of $^{210}\text{Pb}_{\text{xs}}$ shows relatively stable values down to 6 cm and a
219 gently decrease below.

220 4.2. Living benthic foraminifera

221 4.2.1. Living standing stock and ecological indices

222 In total, 476 living individuals were counted representing 31 species among them 15 are
223 calcareous and 16 are agglutinated species. Tests of benthic foraminifera, especially calcareous, don't

224 show any mark of alteration or dissolution. Living faunal standing stocks show extremely low values
1
2 225 in the 63-125 μm size fraction, from 0 ind./100 cm^2 in the shallowest St. 01A to 11 ind./100 cm^2 in St.
3
4 226 03 (Fig. 5a and Fig. 7). For this 63-125 μm fraction, excluding St. 03 (750 m), H' therefore equals 0 and
5
6
7 227 E equals 1 for all stations due to the presence of only one living species (Fig. 5c, d). Benthic
8
9 228 foraminiferal standing stocks and diversities S are generally higher in the $>125 \mu\text{m}$ size fraction,
10
11 229 ranging from 8 to 297 ind./100 cm^2 , and from 3 to 17 species, respectively, with higher values
12
13 230 generally measured at the shallowest stations (Fig. 5a, b). Lowest standing stocks are observed at the
14
15
16 231 deepest stations (8 and 18 ind./100 cm^2 at Sts. 02 and 04, respectively). H' and E values do not
17
18 232 indicate any clear correlation with water depth (Fig. 5c, d). Both indices are minimal at the mid-depth
19
20
21 233 station (St. 03, 750 m).
22

234 4.2.2. Relative abundances of the dominant species

235 Because of the extremely low living standing stock in the 63-125 μm size fraction, relative
26
27 236 abundances and comparison between size fractions should be considered with great care. Except at
28
29
30
31 237 St. 03, only calcareous taxa are found in the 63-125 μm fraction (Fig. 6a). In the $>125 \mu\text{m}$ fraction, the
32
33 238 contribution of agglutinated taxa is decreasing with increasing water depth, ranging from 40 % at St.
34
35
36 239 01A to 0 at Sts. 02 and 04 (Fig. 6b). With the exception of the deepest St. 04 where *Oridorsalis tenerus*
37
38 240 shows high relative abundances in both size fractions, species assemblages are drastically different
39
40
41 241 between size fractions (Fig. 7). Some species observed in the small size fraction are however worth
42
43 242 mentioning: *Parafissurina tectulostoma* and *O. tenerus* are found on the upper slope (Sts. 05 and 03)
44
45 243 and in the lower slope (Sts. 02 and 04). Higher standing stocks in the $>125 \mu\text{m}$ fraction support a
46
47
48 244 more robust description of the species assemblages. *Elphidium excavatum subsp. clavatum* and
49
50 245 *Nonionellina labradorica*, both calcareous species, are the dominant taxa (45 and 13 %, respectively)
51
52 246 in shelf sediments (St. 01A, Fig. 7b). Subordinate agglutinated species consist of *Saccamina* sp.,
53
54
55 247 *Labrospira crassimargo*, *Nonionina scapha* var. *arenacea* and *Recurvoïdes contorta*. Upper and lower
56
57 248 slope stations are characterized by distinct foraminiferal populations. Foraminiferal assemblages at
58
59
60 249 upper slope stations are both overwhelmingly (>60 %) dominated by *Cassidulina neoteretis*.
61

250 *Elphidium excavatum subsp. clavatum* and *Lagenammina arenulata* are present (27 % and 7 %,
1
2 251 respectively), at St. 05 (350m) though both species are absent in the other upper slope St. 03 (750
3
4 252 m). In both deepest Sts. 02 and 04, *Ioanella tumidula* and *Triloculina oblonga* are common to
5
6
7 253 abundant (Fig. 7b). *Oridorsalis tenerus* is dominant (64 %) at the deepest station (St. 04) but not
8
9 254 observed at St. 02.

11 255 4.2.3. Vertical distribution

12
13
14 256 The vertical distribution (0 to 5 cm) of living foraminifera was analysed for the >125 µm size
15
16
17 257 fraction only (Fig. 8). Benthic foraminifera are generally concentrated in the upper 2 cm of the
18
19 258 sediment with density reaching up to 133 and 386 ind./50 cm³ in the top-most layer (0-0.5 cm) of Sts.
20
21
22 259 03 and 05, respectively. At the shallowest St. 01A, the highest faunal density is also observed in the
23
24 260 top-most layer with 47 ind./50 cm³ and abundant agglutinated species, among which *L. crassimargo*
25
26 261 and *N. scapha var. arenacea*. However, contrary to other stations, living faunas are found down to 5
27
28
29 262 cm, with *E. excavatum subsp. clavatum* reaching up to 28 ind./50 cm³ in the 4-5 cm layer.
30
31 263 *Nonionellina labradorica* shows its higher abundances between 1 and 2 cm (12 ind./50 cm³).

33 264 5. Discussion

34
35
36
37 265 In most studies where benthic foraminifera from 63-125 µm and >125 µm size fractions are
38
39 266 analysed, the standing stocks are generally much higher (e.g. [33]). In the Arctic, particularly under
40
41
42 267 permanent sea-ice cover, most of the benthic foraminifera are smaller than 125 µm [78, 102, 103].
43
44 268 However, in this study, the living standing stock in the 63-125 µm size fraction is extremely low and
45
46 269 always much lower than in the >125 µm size fraction. This might be due to either a methodological
47
48
49 270 bias related to the staining of the living foraminifera or to environmental conditions. At all stations,
50
51 271 the sediment is extremely fine (Fig. 3) and therefore very cohesive which might prevent the good
52
53
54 272 penetration of Rose Bengal staining in the sediment. Although we cannot completely rule out this
55
56 273 hypothesis, the occurrence of well stained individuals in the >125 µm size fraction suggests that the
57
58 274 extremely low density in the 63-125 µm fraction is a consequence of environmental conditions rather
59
60
61
62
63
64
65

275 than a methodological bias. Density of dead fauna was assessed on the top centimetre (0-1cm) of the
1
2 276 sediment for the 63-125 and >125 μm fractions in order to test whether the distribution of living
3
4 277 fauna according to the size fractions is representative of mean average conditions in the studied
5
6
7 278 area. Living and dead faunal densities are shown for both fractions in Figure 9. Not surprisingly given
8
9 279 the time interval represented by the accumulation of dead fauna (25 years at least considering a
10
11 280 minimal sedimentation rate of 0.4mm/yr [23]), the density of the dead fauna is much higher than
12
13
14 281 that of the living fauna, especially for the 63-125 μm size fraction. Furthermore, the density of the
15
16 282 dead fauna shows highest values in the lower slope Sts. 02 and 04 while the living fauna are more
17
18
19 283 abundant in the upper slope Sts. 03 and 05. The remobilization and transport of dead fauna by active
20
21 284 currents from shallow to deep settings [23] as well as taphonomical processes leading to the
22
23 285 dissolution of calcareous forms that dominate the living assemblage at shallow stations [e.g., 89]
24
25
26 286 might in part explain the observed discrepancy. More presumably, we consider that the sampling
27
28 287 period (late August to early September 2015) is not typical of normal late summer environmental
29
30
31 288 conditions in the Chukchi Sea and/or that the peak production of benthic foraminiferal species which
32
33 289 contribute to the 63-125 μm fraction does not occur over late summer. Our data does not permit us
34
35 290 to deal further with this issue. Therefore, and despite the relatively high proportion of dead
36
37
38 291 foraminifera in the 63-125 μm fraction, most of the following discussion on the distribution of the
39
40 292 living benthic foraminifera will be based on the >125 μm fraction only.

5.1. Density and diversity of living benthic foraminifera related to primary production

293
48 295 Except at St. 01A, where bottom temperature and salinity are -1.5°C and 33.1 respectively,
49
50
51 296 these two parameters display similar values at all other stations, ranging from 0.2 to -0.5°C and close
52
53 297 to 35.0 (Fig. 2a). Wollenburg and Mackensen [102, 103] have shown that among the various factors
54
55
56 298 controlling the distribution of benthic foraminifera in the Arctic, bottom water mass characteristics
57
58 299 are of minor importance. Likewise, given the equivalent grain size measured at all stations (clay to
59
60 300 fine silt), we do not consider this sedimentological parameter as influential in explaining the

301 observed heterogeneities in species assemblages among stations (Fig. 3). The distribution of living
1
2 302 benthic foraminifera is well known to be influenced by biotic and abiotic factors, among which the
3
4 303 oxygen concentration and food supply are the most important [45, 102, 103]. TOC values in the
5
6 304 studied upper and lower slope stations are fairly stable, ranging from 0.6 to 1.2 %, and agree with
7
8 305 values found by Husum et al. [41] for the central Arctic. Over the shelf (St. 01A), TOC reaches 2.6 %.
9
10 306 However, the standing stock at St. 01A is not particularly high compared with other stations, pointing
11
12 307 out the influence of other parameters than organic matter content alone. Recent studies suggest
13
14 308 that the quality and origin of the organic matter delivered to the seabed play a major role in
15
16 309 controlling benthic foraminiferal ecology [25, 28, 29, 32, 46, 75]. The major food source for benthic
17
18 310 foraminifera in the open ocean is organic matter derived from primary production. In the Arctic
19
20 311 Ocean, food availability and benthic foraminiferal standing stock, composition and vertical
21
22 312 distribution in sediments will greatly depend on sea-ice seasonality (e.g., [41, 102, 103]). In the
23
24 313 Chukchi area, the marine primary production, and thus the export of organic matter to bottom
25
26 314 sediments, is essentially controlled by nutrients availability, seasonal sea-ice extent (e.g., [93]), light
27
28 315 penetration and fresh water input variability [22, 111], these parameters being strongly related.
29
30 316 Many studies suggest that nitrogen availability through nitrate supply tends to control and limit
31
32 317 primary productivity in seasonally ice-covered waters of the Arctic Ocean [58, 74, 92]. Tremblay et al.
33
34 318 [93] showed a clear difference between the Chukchi shelf and Chukchi borderlands in terms of
35
36 319 nitrate maximum at the surface due to perennial stratification in the interior sector. Yun et al. [111]
37
38 320 also showed that primary production is highest in the southern Chukchi Sea and decreases
39
40 321 northward as a result of sea-ice cover and meltwater input mainly. In this study, abundance and
41
42 322 diversity are lower in the deepest stations (Sts. 02 and 04) than in the shelf and upper slope stations
43
44 323 (Sts. 01A, 05 and 03). The living foraminiferal density in the >125 μm size fraction at all stations (Fig.
45
46 324 8) remains however low (from 4 ind./50cm³ at St. 02 to 454 ind./50cm³ at St. 05 for the upper
47
48 325 centimetre) in comparison to other studies in Arctic environments. Wollenburg and Mackensen [103]
49
50 326 reported living benthic foraminiferal densities in the same size fraction ranging from 18 ind./50cm³ in
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

327 the deep Nansen Basin to 1044 ind./50cm³ on the Yermak Plateau. Husum et al. [41] using a slightly
328 smaller size fraction (100 µm-1 mm) provided density values of 0 ind./50cm³ on the Alpha and Gakkel
329 Ridge and more than 6300 ind./50cm³ on the Kara Sea continental margin. The north of the Chukchi
330 Sea is covered by sea-ice 8 months a year from November to June [e.g., 82, 90]. Long sea-ice cover
331 leads to a generally low primary productivity and organic matter flux reducing the living benthic
332 foraminiferal standing stock and the faunal habitat depths in the sediment [11, 69]. Although the
333 sea-ice cover at the time of sampling was scarce for the northernmost deep stations, this may, at
334 least partly, explain the standing stock differences between the relatively rich outer-shelf, upper
335 slope stations and the very poor lower slope stations (Fig. 7). During summer in the Chukchi Sea,
336 heterotrophic processes take over autotrophic processes following nutrient depletion by the spring
337 bloom [39, 99]. This feature induces a seasonal shift in the quantity and the quality of the vertically
338 exported biogenic matter. The biogenic matter exported is high and fresh in spring while it becomes
339 lower and more degraded (faecal pellets, aggregates, detritus) in summer, especially during August
340 and September [99]. Chlorophyll data measured at the deepest stations of the Chukchi Sea, however,
341 show a relatively well-developed subsurface Chlorophyll maximum (SCM) centred around 60 m with
342 chl *a* values reaching 1.6 µg L⁻¹. The depth and values of this SCM agree with the results of Coupel et
343 al. [22] for the Chukchi area and Martin et al. [54] for other Arctic seas. Therefore, surface or
344 subsurface productivity might not be the only limiting factor there.

5.2. Species distribution as a proxy of environmental changes

345 In the 5 studied cores, distinct living benthic foraminiferal assemblages are observed
346 according to the following bathymetric ranges as: outer shelf (110 m water depth), upper slope (350-
347 750 m) and lower slope (2100-2300 m). The outer shelf assemblage is found where organic matter
348 content is the highest (Fig. 3). The most abundant species in this assemblage are *E. excavatum subsp.*
349 *clavatum*, *N. labradorica*, *L. crassimargo* and *R. contorta*. *Elphidium excavatum subsp. clavatum* is a
350 typical shelf species [61] and was found abundant in surface sediment over the Chukchi shelf [64]
351 although this cited study did not distinguish living from dead fauna. Other species in this assemblage

353 such as *N. labradorica* are either linked to elevated fluxes of fresh phytodetritus [14, 21, 67] or
1 associated to high contents of buried organic matter [21]. Phytoplankton bloom in this area typically
2 354 occurs in late June-early July [2], two months before the sampling period. High TOC (Fig. 3) and the
3
4 355 vertical distribution of *N. labradorica* at this station (Fig. 8) rather suggest the latter case in the
5
6 356 present study. From a study conducted over the Kamchatka slope, Bubenshchikova et al. [11]
7
8 357 described *N. labradorica* as an abundant intermediate infaunal species in the sea-ice free
9
10 358 mesotrophic zone. The benthic foraminiferal population observed at the shelf St. 01A is made of 40
11
12 359 % of agglutinated specimens, peaking to 70 % in the topmost centimetre (Fig. 8). This
13
14 360 calcareous/agglutinated assemblage is typical of shallow Arctic and subarctic environments [41, 49,
15
16 361 50, 64, 104]. In the Chukchi Sea, several authors observed undersaturated seawater $p\text{CO}_2$ during the
17
18 362 sea-ice free period across the shelf [3, 4, 5, 15, 16, 30, 59, 66, 81]. In contrast, subsurface seawater
19
20 363 $p\text{CO}_2$ values were highly oversaturated [3, 6]. These observations are indicative of an efficient
21
22 364 organic carbon remineralization in the subsurface waters and into the sediment of the Chukchi
23
24 365 continental shelf. Organic carbon remineralization increases $p\text{CO}_2$ and decreases the pH. This
25
26 366 process contributes to the acidification of interstitial waters making them further corrosive and
27
28 367 leading to partial carbonate dissolution [7, 8] which could explain the recorded high abundance of
29
30 368 agglutinated species on the shelf sediment of the Chukchi Sea.
31
32 369

370 The upper slope assemblage is highly dominated by *C. neoteretis*. *Elphidium excavatum*
371 *subsp. clavatum* is dominant only on the upper slope St. 05. *Cassidulina neoteretis* is a shallow
372 infaunal species associated to AIW in the Arctic [41, 42, 64] and typically related to fresh input of
373 phytodetritus [34, 53]. Additionnaly, and although based only on quick visual examination of dead
374 faunas, we notice that *C. neoteretis* that is dominating the living fauna at Sts. 03 and 05 is completely
375 absent in the dead fauna. *Cassidulina*, a typically opportunistic genus, is however generally more
376 abundant in dead assemblages than in living populations in various settings of the world ocean as a
377 consequence of high production rates and short living time [26]. Our paradoxical observations may
378 be related to dissolution in sediment by corrosive interstitial water or active transport by bottom

379 currents directly after the death of the organisms as already suggested earlier to explain higher
1
2 380 density of the dead fauna at deep stations. The presence of this species, indicator of modified
3
4 381 Atlantic Water/Arctic Intermediate Water [43], in the living fauna only may also suggests very recent
5
6
7 382 changes in the local hydrology. *Elphidium excavatum subsp. clavatum* was observed by Korsun and
8
9 383 Hald [47] in the Tempelfjorden in Svalbard and seems to be related to increasing glacier meltwater
10
11 384 discharge. It is a widespread species in Arctic shelves with ability to colonize harsh environments
12
13
14 385 (e.g., [21]). Its presence in the living fauna (Fig. 7b and 8 may therefore suggest high meltwater
15
16 386 supply from sea-ice at the location of Sts.01A and 05.

17
18
19 387 The deep assemblage is essentially made of the surface infaunal species *O. tenerus* and *I.*
20
21 388 *tumidula*. *Ioanella tumidula* dominates St. 02 at 2100 m while *O. tenerus* is absent. *Oridorsalis*
22
23 389 *tenerus* is overwhelmingly dominant at the deepest St. 04. Note that *O. tenerus* is the only species
24
25
26 390 found at both Sts. 02 and 04 in the 63-125 μm fraction. *Oridorsalis tenerus* and *I. tumidula* (as
27
28 391 *Eponides tumidulus*) were found in the same biofacies by Ishman and Foley [42] at water depths
29
30
31 392 greater than 1300 m in the Canada Basin. Husum et al. [41] also found these species in the 1300-
32
33 393 3700 m water depth interval, on the permanently ice-covered Lomosov Ridge and Alpha Ridge in
34
35 394 addition to the seasonally ice-free Nansen Basin. They are therefore referred as typically oligotrophic
36
37
38 395 species. Wollenburg and Mackensen [102] however suggest that *O. tenerus* is better adapted to
39
40 396 more oligotrophic conditions. Lower TOC values at St. 04, where *O. tenerus* is dominant, compared to
41
42 397 St. 02 well supports this idea.

43
44
45 398 The vertical distribution of the living fauna (Fig. 8) shows sharp decrease below the first
46
47 399 centimetre with the topmost layer being normally the richest, except at St. 02 where no living
48
49
50 400 individuals were found in this upper layer. This is very consistent with other studies on the
51
52 401 distribution of living benthic foraminifera in the Arctic. Wollenburg and Mackensen [103] found living
53
54 402 individuals down to 8 cm while in the central Arctic most of the fauna was concentrated in the upper
55
56
57 403 2 cm according to the very low flux of organic matter in this permanently ice-covered area. The
58
59 404 sampling period during post-bloom conditions, as well as the relatively low TOC values measured in
60

405 sediments of the upper and lower slope stations suggest that a weak input of labile organic matter in
406 this sector of the Chukchi Sea induced the observed shallow (upper 2 cm) habitat of benthic
407 foraminifera. The shallow St. 01A is characterized by a subsurface peak in foraminiferal density
408 between 1 and 3 cm with *N. labradorica*, an intermediate infaunal species [61] as the dominant taxa.
409 The presence of *E. excavatum subsp. clavatum*, a shallow infaunal species between 3 and 5 cm at St.
410 01A suggests local bioturbation or bio-structures. The occurrence at this station of several macro-
411 organisms such as bivalves and echinoderms as well as a homogeneous $^{210}\text{Pb}_{\text{xs}}$ activity profile (Fig. 4)
412 showing relatively stable values down to 6 cm confirms the possible bioturbation or bio-structure
413 systems created by the activity of macro-/meio-fauna. On one hand, bioturbation might explain the
414 unusual occurrence of *E. excavatum subsp. clavatum* deeper than expected. On the other hand, the
415 presence of bio-structures leads to particular biochemical conditions and biotic associations which
416 offer microhabitats favourable for the development of benthic foraminifera traditionally found in
417 another range of sediment depth [52] such as *E. excavatum subsp. clavatum*.

419 6. Conclusions

420 This study aims to describe and understand the distribution of living benthic foraminifera in
421 the northern Chukchi Sea continental shelf, upper and lower slope, an Arctic environment strongly
422 impacted by recent climate changes. According to our observations, various environmental factors
423 may influence the benthic foraminiferal abundance, composition and vertical distribution in the
424 Chukchi Sea.

- 425 (1) The distributional patterns of living faunal assemblages seems to reflect the nature of the
426 bottom water masses according to the three bathymetric sectors of the Chukchi Sea
427 investigated in the present study. Over the shelf bathed by the corrosive Pacific water
428 agglutinated specimens are abundant. Here, the assemblage is dominated by the calcareous
429 species *E. excavatum subsp. clavatum* and *N. labradorica* and the agglutinated species *L.*
430 *crassimargo* and *R. contortus*. Over the Chukchi slope, under the influence of Atlantic waters,

431 the assemblage is overwhelmingly dominated by *C. neoteretis*. Benthic foraminiferal
1
2 432 populations in deep stations bathed by Arctic water are dominated by *I. tumidula* and *O.*
3
4 433 *tenerus*.

5
6
7 434 (2) The overall low faunal diversity and standing stock at all stations may reflect post-bloom
8
9 435 conditions in late August and early September in the area, and hence reduced supply of fresh
10
11 436 organic matter to the sea floor. Living standing stocks are much lower in the 63-125 μm size
12
13 437 fraction than in the $>125 \mu\text{m}$ fraction. Although a methodological bias cannot be completely
14
15 438 excluded, we believe that the conditions at the time of sampling were oligotrophic with
16
17 439 highly degraded organic matter that does not favour the presence of opportunistic species
18
19 440 often found in the small fraction.
20
21

22
23 441 (3) Our results suggest that in the context of post-bloom conditions, the lower quality of
24
25 442 exported organic matter might also explain the observed, exclusively shallow (topmost
26
27 443 centimetre) habitat of living benthic foraminifera in sediments of the upper and lower slope.
28
29 444 The apparently deepest habitat (down to 5 cm) found over the shelf is probably related to
30
31 445 intense bioturbation or bio-structures in this shallow setting, as evidenced by the presence of
32
33 446 typical surface dwellers down in the sediment column.
34
35

36
37 447 Our study brings several hypothesis on the ecology and preservation of benthic foraminiferal
38
39 448 fauna in the northern Chukchi Sea, confirming the key information that this species group can
40
41 449 provide about modern and past changes in Arctic circulation and climate.

721 Table and figure captions

722 **Table 1** Station numbers, types, locations and water depths

723 **Fig.1** Bathymetric map of the Chukchi Sea with sampling locations, main features of the surface and
intermediate circulation, and mean sea-ice extent in August 2015 (white line) and September 2015
(white dotted line). The circulation is adapted from Rudels and al. [73]. For the surface waters, low-
salinity currents derived from Pacific water are indicated by green arrows and cold polar and arctic
currents by blue arrows. Circulation of intermediate waters is shown by black dotted arrows. AC:
Anadyr Current; ACC: Alaskan Coastal Current; BG: Beaufort Gyre; BSW: Bering Sea Water; SCC:
Siberian Coastal Current; TPD: Transpolar Drift. Monthly sea-ice extent is from NSIDC [27] and
bathymetry is from IBCAO, WGS84

731 **Fig.2** Water column profiles of temperature, salinity (a) and chlorophyll a (b) at Sts. 01A, 03, 02 and
04. Pacific water mass is underlined in green, Atlantic Intermediate Water in red and Arctic Deep
Water in blue

734 **Fig.3** Downcore (topmost 2 cm) profiles of median sediment grain size D_{50} (μm), total organic carbon
content (TOC, wt. %), total nitrogen content (TN, wt. %), $\delta^{13}\text{C}_{\text{org}}$ (‰ VPDB) and C/N ratio at all
stations

737 **Fig.4** Downcore $^{210}\text{Pb}_{\text{xs}}$ profile measured at St. 01A

738 **Fig.5** Ecological indices describing foraminiferal assemblages at all stations for the 63-150 μm
(topmost centimetre, grey bars) and >125 μm size fractions (topmost 5 cm, black bars). (a)
Foraminiferal abundances; (b) Number of species S ; (c-d) Shannon (H') and Evenness (E) indices

741 **Fig.6** Proportion of agglutinated versus calcareous species at all stations for the 63-125 μm size
fraction (a) and the >125 μm size fraction (b)

743 **Fig.7** Foraminiferal relative abundances of major species ($>5\%$ of the total living benthic foraminifera
assemblage) for the 63-125 μm (a) and the >125 μm (b) size fractions. Living standing stock (number
in the central area of the pie charts) are standardized for a surface area of 100cm^2 . Species
representing less than 5 % are grouped in the category “others”

747 **Fig.8** Vertical distribution of major species of living benthic foraminifera (>125 µm) in terms of faunal
1
2 748 density (ind./50cm³) in the topmost 5 cm
3

4 749 **Fig.9** Density of living (blue) and dead (orange) benthic foraminifera in the first centimetre of
5
6
7 750 sediment for each station and each size fraction.

Appendices

Appendix 1 Taxonomic reference list of major taxa

Cassidulina neoteretis Seidenkrantz, 1995

Elphidium excavatum subsp. clavatum Cushman, 1930

Ioanella tumidula (Brady, 1884)

Labrospira crassimargo (Norman, 1892)

Laevidentalina elegans (d'Orbigny, 1846)

Lagenammia arenulata (Skinner, 1961)

Quinqueloculina arctica Cushman, 1933

Nonionellina labradorica (Dawson, 1860)

Nonionina scapha var. arenacea Heron-Allen and Earland, 1922

Oridorsalis tenerus (Brady, 1884)

Parafissurina tectulostoma Loeblich and Tappan, 1953

Psammophaga sp. Arnold, 1982

Recurvoides contortus Earland, 1934

Saccammia sp. Sars, 1869

Triloculina oblonga (Montagu, 1803)

Appendix 2 Plate with SEM pictures of major species (>125 µm)
